PREFACE TO THE FOURTH EDITION

THIS work has been revised throughout, but its general principles remain the same as those referred to in the Preface to the First Edition. Changes in the letterpress, several new articles, and additions to the illustrations which now number 701, of which 179 are coloured have inevitably increased the number of pages: but it has been thought better to continue the book as a single volume rather than to publish it as two, in view of the many cross-references that are necessary when the same disease is discussed in different places under the headings of the various symptoms it may produce.

The chief difficulty in the revision has been to decide, not what to include, but what to leave out. New tests and new methods of examination multiply annually: some prove reliable: others, after a temporary vogue, lapse from practice because time proves them to be fallacious. Practical utility in diagnosis has been the criterion for inclusion.

Death has claimed Sir Malcolm Morris, Sir Frederick Taylor, and Dr. F. J. Smith, contributors to the First Edition: it is a source of profound regret that their names no longer appear in the list of writers on page ix. Cordial thanks are extended to all whose names are in that list, for the help they have given with the letterpress: gratitude goes out also to many other helpers, including those who have generously supplied illustrations, and whose names are given in the list on page xii: also to Dr. William Byam, O.B.E., for revising those parts of the work which deal with tropical diseases: to the publishers, Messrs. John Wright & Sons, of Bristol, for the assiduous care they have taken in the production of the work: and, by no means least, to the unnamed men in the printing works who had no mean task to deal with when they set up the type for the meticulous index with, one believes, extremely few mistakes.

Delays in connection with the revision have led to the book being out of print for over five years. The facts, however, that over thirty thousand copies of previous editions have been sold, and that the work has been translated both in Italy and in Spain, would seem to testify to its usefulness: and it is hoped that the present edition will prove of as much service to the medical profession as its predecessors appear to have been.

HERBERT FRENCH.

London,

September, 1928.

PREFACE TO THE FIRST EDITION

THIS book is a treatise on the application of differential diagnosis to all the main signs and symptoms of disease. It aims at being of practical utility to medical men whenever difficulty arises in deciding the precise cause of any particular symptom of which a patient may complain. It covers the whole ground of medicine, surgery, gynaecology, ophthalmology, dermatology, and neurology.

Whatever the disease from which a patient is suffering, the importance of diagnosing it as early as possible can hardly be over-rated. The present volume deals with diagnosis from a standpoint which is different from that of most text-books, having been written in response to requests for an *Index of Diagnosis* as a companion to the publishers' *Index of Treatment*, issued in 1907. The book is an index in the sense that its articles on the various symptoms are arranged in alphabetical order; at the same time it is a work upon differential diagnosis in that it discusses the methods of distinguishing between the various diseases in which each individual symptom may be observed. Whilst the body of the book thus deals with *symptoms*, the general index at the end gathers these together under the headings of the various *diseases* in which they occur.

The Editor lays particular stress upon the importance of using these two parts of the book together. Unless reference is made freely to the general index, the reader may miss a number of the places in which is discussed the diagnosis of the disease with which he has to deal; for while each *symptom* is considered but once, each *disease* is likely to come up for discussion under the heading of each of its more important symptoms.

The guiding principle throughout has been to suppose that a particular symptom attracts special notice in a given case, and that the diagnosis has to be established by differentiating between the various diseases to which this symptom may be due. One of many difficulties arising during the construction of the work was that of deciding where to draw the line as regards symptoms themselves. The exclusion of many borderline headings such as "Dullness at the base of one lung," "Inability to breathe through the nose," and various signs such as Romberg's, Stellwag's, von Graefe's, and so forth, may perhaps seem arbitrary; but reference to the minor symptoms and physical signs which have not been thought sufficiently important to merit separate articles will be found in the general index at the end of the volume.

Treatment, pathology, and prognosis are not dealt with except in so far as they may bear upon differential diagnosis—the employment of salicylates, for instance, in distinguishing acute rheumatic from other forms of arthritis; the use of the microscope in distinguishing malignant neoplasms from inflammatory or other tumours; the value of the lapse of time in distinguishing between tuberculous and meningococcal meningitis.

Coloured plates and other illustrations have been introduced freely wherever it was thought they might be helpful in diagnosis. Most of them are original, but

a few are reproduced from other sources, and thanks are due to the authors and publishers who have kindly lent them.

So far as the Editor is aware, although there exist indices of symptoms, and medical works in which various maladies are discussed in alphabetical order, the present Index of Differential Diagnosis of Main Symptoms is unique in medical literature. It rests with the medical profession to decide whether it strikes the mark at which it aims. There must be room for improvement in many respects notwithstanding the great amount of time and labour that have been bestowed upon it.

However this may be, the work undoubtedly owes much of what value it possesses to the suggestions and kindly help of the many contributors who have assisted in its making; and to the practitioners and the authorities of various institutions who have generously lent the material for many of the illustrations. Indeed, it is difficult to see how the book could have been produced in its present completeness without their willing collaboration: they are enumerated elsewhere, and to all of them the Editor tenders his sincere thanks.

Criticisms and suggestions are invited, and will be received with gratitude by the Editor,

HERBERT FRENCH.

AN INDEX OF DIFFERENTIAL DIAGNOSIS OF MAIN SYMPTOMS

ABDOMEN, RIGIDITY OF. (See RIGIDITY OF THE ABDOMEN, p. 734.)

ABDOMINAL PAIN. (See PAIN, ABDOMINAL, p. 524.)

ABDOMINAL SWELLING. (See SWELLING, ABDOMINAL, p. 804.)

ABDOMINAL VARICOSE VEINS. (See VEINS, VARICOSE ABDOMINAL, p. 908.)

ACCENTUATION OF HEART SOUNDS. It may be that one or other of the heart sounds is much louder than it ought to be. It is the first sound that is likely to be accentuated or prolonged at the impulse; whilst in the second right, or second and third left intercostal spaces close to the sternum, it is the second sound that is likely to be accentuated rather than the first. It is unusual to find the first sound accentuated at the base or the second sound at the impulse, unless there is at the same time still greater accentuation of the first sound at the impulse, and of the second sound at the base respectively. The three conditions under which accentuation of a cardiac sound is clinically important are: (1) *When the second sound is unduly loud in the second right intercostal space close to the sternum*; (2) *When there is accentuation of the second sound in the second left intercostal space close to the sternum*; (3) *When there is accentuation of the first sound at or near the impulse.*

1. **Accentuation of the second sound in the second right intercostal space** close to the sternum usually indicates that the systemic blood-pressure is above the normal, and the sphygmomanometer will determine this. Other factors in the case will be relied upon in deciding whether a rise of BLOOD-PRESSURE (p. 105) is due to age, arteriosclerosis, granular kidney, or other cause. With very high blood-pressure the aortic second sound may have almost a clanging or ringing character. Somewhat similar accentuation may occur, however, without any material increase in blood-pressure when the aortic valves have become rigid from senile atheromatous or calcareous changes, in which case the first aortic sound is often followed by a blowing systolic bruit. The differentiation depends upon the sphygmomanometer reading.

2. **Accentuation of the second sound in the second left intercostal space** close to the sternum—accentuation of the pulmonary second sound—indicates a higher pressure than there should be in the pulmonary circulation, except in children in whom it is not uncommon to find the pulmonary second sound normally much louder than the aortic. The most important cause of pathological accentuation of the pulmonary second sound is disease of the mitral valve, especially mitral stenosis with good compensation of the right heart. Sometimes the pulmonary second sound instead of being accentuated is reduplicated (p. 729); and in the same patient there may be reduplication at one examination, accentuation without reduplication at another. The cause of an accentuated or reduplicated pulmonary second sound will generally be obvious from the other cardiac physical signs. One way in which it may have particular significance is in distinguishing between old and recent changes in the mitral valve: when, for instance, a systolic and mid-diastolic bruit at the impulse are due to recent endocarditis which may possibly clear up, there is very

much less accentuation of the pulmonary second sound than there would be if the same bruits were due to mitral stenosis and regurgitation due to old fibrotic changes.

3. **Accentuation of the first sound at the impulse** may have one or other of two entirely different characters: it may be an accentuation of very short duration, difficult to describe in words, though obvious enough when heard, and often spoken of as a 'slapping' first sound: this is always suggestive of *mitral stenosis*. It may occur when there is neither a presystolic nor a mid-diastolic bruit, though even when there is a bruit the slapping character of the first sound may still be distinguished. When there is failure of compensation in a mitral case the driving power of the heart may become so feeble that bruits are no longer audible, the action may be quite irregular from auricular fibrillation, and yet the occurrence of this slapping first sound here and there in an otherwise tumbling rhythm may suggest the existence of mitral stenosis.

The second variety of accentuation of the first sound at the impulse consists in its being very much longer than it ought to be—a marked prolongation of the first sound as distinct from there being any bruit. It indicates that there is considerable hypertrophy of the left ventricle, and it is common with arteriosclerosis, chronic nephritis, and raised blood-pressure, when it is often associated with an accentuated aortic second sound; but it may accompany other forms of cardiac hypertrophy such as that met with in chronic alcoholics, or with adherent pericardium, or aortic stenosis or regurgitation; or as the result of long-continued strenuous physical work with enlarged heart of the athlete's, blacksmith's, stoker's, or other occupational type.

Transient accentuation of the first sound at the impulse may occur in nervous patients examined while their hearts are acting rapidly: it vanishes in a few minutes when the patient becomes less nervous and the heart slower. The phenomenon is common in connection with life insurance examinations.

Herbert French.

ACCOUCHEUR'S HAND is seen characteristically in *tetany* (*Fig. 1*), though it may also occur in other spasmodic neuro-muscular affections such as *athetosis*, *neurosis*, and *hysteria*. In a typical case, the attitude of the fingers is almost pathognomonic. There is full extension of all the fingers and of the thumb at the interphalangeal joints, the four fingers are adducted firmly towards the middle finger, so as to form a cone, they are

Fig. 1. The hand in tetany. The patient's left hand is in its natural position: the right is being held up by a nurse to show the palmar aspect. (From a photograph by Dr. Donald Peterson.)

semiflexed at the metacarpo-phalangeal joints, and the thumb is strongly adducted and opposed to the cone of which the middle finger forms the apex, or else into the palm of the hand. The spasmodic muscular contraction seldom ceases here, but generally affects the rest of the arm also, the wrist being flexed and abducted towards the ulnar side, the elbow flexed to a right angle, and the arm rotated inward and adducted so as to lie in contact with the trunk. The affection is generally symmetrical in tetany, but may be unilateral when due to athetosis or to functional causes. In tetany the feet and ankles are apt to show similar spasmodic contractions, the ankle being fully plantar-flexed, the toes and the distal half of the feet rotated inward, the knees extended rigidly, and generally the thighs also. The contractions may be limited to the hands and feet—the so-called *carpo-pedal spasm*—especially in the tetany of young children suffering from rickets or from gastrointestinal disorder such as diarrhoea. When

adults are affected, the symptoms spread from the limbs to the trunk, the whole body being kept rigidly extended, the paroxysms lasting from a few minutes to many hours, and recurring for days, weeks, or even months. So far as the tetany itself is concerned recovery is invariable, though the patient may sometimes succumb to the associated malady, tetany itself being generally not a primary disease but a complication of dietetic

errors, rickets, gastric ulcer, gastrectasis, colitis, intestinal fermentation or putrefaction, thyroidectomy, chronic renal dwarfism, or pregnancy. The diagnosis is seldom difficult.

One remarkable feature of the case is that in the intervals between the spasms, if the upper arm is grasped firmly between the observer's two hands, and the pressure maintained, the hand and wrist may be forthwith sent into the typical spasm—Trousseau's sign. If the cheek close to the front of the ear is percussed gently but sharply from above downwards the different groups of muscles supplied by the branches of the *pes anserinus* of the seventh nerve can be made to twitch successively: Chvostek's sign. The muscles of the limbs often show altered electrical reactions in that, though still responding to faradism, with galvanism A.C.C. is greater than K.C.C. Erb's sign.

Children affected by the carpo-pedal spasms of tetany often maintain the curious position of the hands and feet for days continuously, without the acute paroxysms of the tetanoid phenomena that adults are apt to exhibit: on the other hand, they are more prone than adults to suffer from other spasmodic phenomena—especially laryngismus stridulus or convulsions—as alternatives to, or concomitants of, the carpo-pedal spasms: a condition of affairs described as 'spasmophilia'.

Herbert French.

ACETONURIA denotes the occurrence of acetone in the urine in amounts to be detected by ordinary clinical tests. In practice the laboratory method of distilling the urine to get the acetone in concentrated solution takes too long, and yet without distillation it is difficult to apply the iodoform test: for clinical work one uses Legal's nitroprusside test, or Rothera's modification of it (*Figs. 2-8*). Legal's test consists in taking 5 c.c. of urine in a test-tube, adding a few drops of liquor sodæ, then a few drops of fresh sodium nitroprusside solution, and finally acidifying with strong acetic acid. The liquor sodæ causes no change of colour, or at most an opalescence from the precipitation of phosphates: the sodium nitroprusside produces a reddish-brown colour in almost all urines owing to the presence of creatinine: if the red colour is due to creatinine only it is discharged on adding acetic acid, whereas when acetone is present the red deepens to a rich burgundy. Rothera's modification of this test (*Fig. 8*) consists in adding a few drops of fresh nitroprusside solution to 5 c.c. of urine, liquor ammoniæ till the mixture is decidedly alkaline, and then ammonium sulphate crystals in excess: as the solution becomes saturated with the latter a colour like that of potassium permanganate develops if acetone is present, the maximum being reached in about fifteen minutes.

Acetone is very frequently associated with diacetic acid and oxybutyric acid: the detection of these, however, does not afford any clinical information that is not afforded by the acetone test. The tests for the butyric acids are difficult. That for diacetic acid (p. 214) is even easier than the acetone tests, and many clinicians are content to test for diacetic acid and not for acetone, the information afforded being much the same. When these substances are being passed in the urine the patient is said to be suffering from *acidosis*, the result of unnatural metabolism. This occurs in the most extreme degree in certain cases of diabetes mellitus. The same patient may, of course, pass acetone in his urine at one time and not at another: the prognosis is always graver, however, when acetone is present. A patient without acetonuria is in no immediate danger of coma, whereas, when acetone is present as well as sugar, coma may supervene at any time.

Acetonuria may occur, however, without glycosuria: even a healthy person who is starved of carbohydrate food is apt to pass acetone and diacetic acid in the urine. This explains why it is that acetonuria occurs in such conditions as gastric ulcer: gastric carcinoma: gastrectasis: œsophageal stenosis: intestinal obstruction: cachexia, whether tuberculous, malignant, syphilitic, or malarial: in cases of persistent vomiting of pregnancy: uræmia: severe migraine: infantile diarrhœa and vomiting: cyclical vomiting of children (p. 479): concussion: acute alcoholism: ptomaine poisoning: delirium tremens: tabes dorsalis with severe and prolonged gastric crises: and probably in many other conditions in which there is either actual or virtual starvation. This used to apply to surgical operations under anæsthetics—the patient was often starved beforehand, and then be persistently sick afterwards: many who have been under a general anæsthetic for any length of time have temporary acetonuria, and in some the acidosis increases instead of being transient, this being part of the pathology of delayed chloroform poisoning.

Acetonuria may also result from gross intracranial lesions, such as cerebral or cerebellar

tumour, with much vomiting : or with tuberculous meningitis : or encephalitis lethargica : and it may be pronounced even as early as the first two or three days in acute cerebrospinal meningitis.

The chief importance of acetonuria from a diagnostic point of view lies not so much in distinguishing one disease from another as in detecting the existence of acidosis. The

(*Figs. 2 and 5,* normal urine; *Figs. 3 and 6,* the appearance after adding caustic soda and sodium nitroprusside; *Figs. 4 and 7,* the appearance after adding acetic acid, *Fig. 4* being positive, and *Fig. 7* negative for acetone.) *Fig. 8.*—Roth's test for acetone.

importance of this from the point of view of prophylaxis and treatment will be obvious when it is remembered that acidosis does not occur until the liver and tissues have lost their glycogen, and that glycogen storage depends largely upon the ingestion of carbohydrates and their proper metabolism.

ACIDOSIS.—(See ACETONURIA, p. 3.)

ACROPARÆSTHESIA.—(See PAIN IN THE EXTREMITY (UPPER), p. 543.)

AGEUSTIA.—(See TASTE, ABNORMALITIES OF, p. 859.)

ALBUMINURIA.—This term is used to denote the passage in the urine of protein that is coagulable on boiling. More than one substance is included in this sense, and there

are varying proportions of albumin and globulin in different cases. So variable may be the relative amounts of these, not only in different diseases, but also in different cases of the same disease, and in the same patient at different times, that little useful clinical information is to be obtained by dealing with them separately, at any rate so far as present knowledge goes; though it would seem that when globulinuria preponderates over albuminuria the prognosis is less unfavourable. Nucleo-albumin (p. 524) comes in quite a different category; and so does albumose (p. 20).

Although numbers of tests for albumin have been devised and advocated, for clinical purposes there is little need to trouble about more than the two common ones, namely (1) *The acetic acid and boiling*, and (2) *The cold nitric acid tests*. It is true that each of these has fallacies; but the fallacies are not common to both, and therefore if there is doubt in the interpretation of one of the two tests, it can be confirmed or otherwise by the other. More delicate tests exist, but there is such a thing as too great delicacy in a clinical method. One does not want to find albumin in minute traces where it does not matter; and it seldom matters until its amount is sufficient to give both the common tests.

1. The Acetic Acid and Boiling Test.—A test-tube three parts full of urine—cleared by filtration if need be—is held by its lower end whilst its upper part is heated carefully to boiling point. It is best not to add acetic acid before boiling unless the specimen is alkaline, in which case it should be acidulated with a drop of acetic acid. After boiling, the tube should be held in a good light against a dark background, such as the sleeve of one's coat; any opalescence will be obvious, and there may be a dense white cloud. Except in rare cases of Bence-Jones albumosuria (p. 21), this will be due to one or more of three things, namely, calcium and magnesium phosphate, calcium carbonate, or coagulated albumin or globulin. One, two, or more drops of acetic acid solution (B.P.) are now added: if the cloud disappears entirely, quickly, and at once, it was due to earthy phosphates, and no albumin is present; if it disappears entirely but with brisk effervescence, the latter is due to calcium carbonates amongst the phosphates, and no albumin is present; if, on the other hand, the cloud clears up but partially, or remains unaltered, or actually increases and becomes more flocculent, albumin is almost certainly present. There is only one serious fallacy remaining, and that is in regard to nucleo-protein: this is precipitated by acetic acid, and it is possible for a cloud of phosphates to be cleared up by the latter and yet for a faint cloud of nucleo-protein to come down in the place of the phosphates in such a way as to suggest that the original cloud was not wholly soluble in the acid, and therefore that albumin is present when it is not. There are three ways of obviating this source of fallacy: the first is to add a single drop of dilute non-fuming nitric acid to the suspicious cloud that remains after adding the acetic acid; if it is due to albumin it will persist or even increase, whilst if it is due to nucleo-protein the nitric acid will disperse it; the second is to perform the cold nitric acid test for albumin as described below—nucleo-protein will not give a definite localized white ring with it; and thirdly, a control test may be done, acetic acid being added to another specimen of the urine without boiling, and the cloud due to any nucleo-protein present compared with the cloud in the acidulated and boiled specimen.

2. Heller's Cold Nitric Acid Test.—About an inch and a half of urine is poured into a test-tube, the latter is held much inclined, and colourless nitric acid is allowed to flow gently down the side until about one-third as much as the urine has been added. The nitric acid is heavier than urine and goes to the bottom: if albumin is present a white ring forms at the junction of the two fluids. Some prefer to pour the nitric acid into the test-tube first, and then add the urine with a pipette. It is important not to shake the tube, or the nitric acid and urine will mix and there will be no definite junction line between them. Fuming nitric acid must be avoided because the nitrous oxide fumes decompose the urea and the resultant bubbles mix the fluids; sometimes there is bubbling even when the nitric acid is colourless, in which case this is due to CO_2 set free from carbonates. The test is very delicate; if any large quantity of albumin is present, the ring appears at once; if there is only a trace, the white ring may not appear for a little, and the tube should be set aside and looked at again in a few minutes. Broadly speaking it takes three minutes for the white ring to develop when the amount of albumin is 1 part in 30,000. This test is open to more fallacies, however, than the acetic acid and boiling test, so that it should

not be trusted alone unless it is negative. In concentrated urines it is common to get a dark-brown, reddish-brown, or violet-brown ring of colour at the junction ; this is nothing to do with albumin ; it is generally most marked in cases of INDICANURIA (p. 395). A white ring, more or less like that due to albumin, may also be due to any of the following :

i. *Resin*.—If the patient is taking copaiba or other similar drug, enough of the resin may be excreted in the urine to form a diffuse white cloud above the nitric acid. This fallacy is best avoided by bearing it in mind and checking the nitric acid test by the heat test ; this latter safeguard applies to all cases of suspected albuminuria.

Fig. 9.—Finely granular casts.

Fig. 10.—Fatty casts.

Fig. 11.—Waxy casts.

Fig. 12.—Blood casts.

ii. *Albumoses*.—These generally occur in association with albumin ; should they occur alone the ring will disappear with warming, to reappear with cooling, and there will be no cloud with the heat test.

iii. *Bence-Jones's Albumose*.—This gives a white ring with nitric acid that disappears on warming, to reappear on cooling ; with the heat test, a dense cloud appears about 60° C., to disappear on further heating to boiling-point (p. 21).

iv. *Nucleo-albumin*.—The ring with this is not in contact with the nitric acid, but higher up, and diffuse ; it may be a real difficulty in diagnosis from albumin, for it is also precipitated by acetic acid, and may therefore give a haze with the boiling test (*see above*).

v. *Urates*.—These may form a cloud near the nitric acid if the urine is very concentrated ; the cloud will disappear on gentle warming, to reappear on cooling, so that it

may also be mistaken for albumose ; the fallacy may be avoided by diluting the urine with plain water before the nitric acid test is employed.

vi. *Urea Nitrate*.—If the urine contains a large percentage of urea a crystalline deposit of urea nitrate may form at the junction ; as a rule the crystalline nature of the ring is obvious on inspection ; but in case of doubt the urine should be diluted and the test repeated.

It does not matter which test is most relied upon when the result is negative ; but before the positive deduction that a urine contains albumin is drawn, both the acetic acid and boiling, and the cold nitric acid tests, should be positive.

Fig. 13.—Epithelial casts.

Fig. 14.—Hyaline casts.

Fig. 15. Mucous cylindroids from urine, not to be mistaken for renal tube-casts, and not necessarily of pathological significance. They are commonly the after-result of gonorrhoea or inflammatory infection of the lower urinary tract, particularly of crypts or haemae in the prostate or urethra ; they do not indicate renal disease.

Fig. 16.—A pus or leucocytic cast.

If it is desired to apply extra-careful tests for the exclusion of albuminuria, either the salicyl-sulphonic acid test or Spiegler's mercuric chloride test may be applied. The former consists in using a saturated solution of salicyl-sulphonic acid and adding a few drops to a little perfectly clear urine in a test-tube, closing the mouth of the latter with the thumb, and then shaking. If no opalescence results, all forms of protein other than peptone can be excluded ; proteins other than peptone give an opalescence of varying degree. Spiegler's reagent consists of mercuric chloride 4 grm., tartaric acid 2 grm., glycerin 20 grm., and distilled water to 100 c.c. A little of this is poured into a test-tube, and some of the urine, cleared by filtration and acidulated with a drop or two of acetic acid, is pipetted on to

the surface: if no opalescence occurs at the junction all proteins other than peptone can be excluded. The trouble with both these tests is that, unless they are negative, they are so delicate that it is difficult to say whether a positive result signifies albumin, globulin, or nucleo-protein. If they are negative, however, one may be quite certain that the urine contains no albumin.

In arriving at a diagnosis of the precise cause of albuminuria in any given case, *it is essential that a microscopical examination of the centrifugalized deposit from the urine should be made.* Whatever else may be found, the first question to be answered is: Are renal tube-casts present as well as albumin, or not? All cases of albuminuria may be divided into two main groups, namely: (I) *Cases with renal tube-casts*; (II) *Cases without renal tube-casts.*

Renal Tube-casts.—When one speaks of renal tube-casts, however, one has to bear in mind that modern methods of centrifugalizing with electrically-driven machinery have reached such perfection that hardly anything that a specimen of urine contains escapes detection: technique has become almost too perfect; for when clinical methods become too delicate they begin to lose some of their clinical value. The result, in connection with casts, is that even in a great many normal urines an occasional renal tube-cast and an occasional red blood-corpuscle are found: therefore when one speaks of cases of “albuminuria with tube-casts”, one means “with enough renal tube-casts to be pathological”. The observer learns from experience to know when the ‘occasional’ tube-cast is inside or outside the normal limits. More than one examination may be required, and the urine should be as fresh as possible, for casts disintegrate on standing, especially in hot weather and in alkaline urines.

Renal tube-casts are of various sorts, and a certain amount of help can be derived from a knowledge of the particular kinds of casts present in a given case. Their matrix or foundation is a structureless material whose origin is obscure, though thought to be due to some kind of protein coagulation. Sometimes the casts consist of this structureless matrix only, and according as they are then less or more highly refractile, they are spoken of as *hyaline casts* (Fig. 14) or *waxy casts* (Fig. 11) respectively. The hyaline is commoner than the waxy, but neither is characteristic of any particular disease. Embedded in the hyaline matrix there may be various substances or structures: and according to the main features of the embedded substances the casts receive different descriptive names. If renal epithelial cells predominate, the cast is an *epithelial cast* (Fig. 13); if leucocytes or pus corpuscles, a *leucocytic cast* (Fig. 16); if red blood-corpuscles, a *blood cast* (Fig. 12); if bacteria, *bacterial casts*; if fat globules, probably derived from degenerated renal cells or leucocytes, *fatty casts* (Fig. 10); if non-fatty granular debris, *granular casts* (Fig. 9). It is not at all uncommon to find a long cast which in one part is simply hyaline, at one end is granular, and at the other epithelial—a *mixed cast*. Upon

one may say that the hyaline cast occurs in all forms of nephritic conditions, whether acute or chronic: that epithelial and leucocytic casts indicate active catarrh: that granular casts tend to occur along with epithelial casts, but that when they occur alone or in association with hyaline casts they are evidence of at least less acute mischief than are epithelial casts; whilst fatty casts come between the two. Blood casts may occur in almost any variety of renal hæmorrhage, and by themselves they are not evidence of inflammation, though in association with other casts they indicate very acute inflammatory changes.

I.—ALBUMINURIA WITH RENAL TUBE-CASTS.

When it has been decided that there are a pathological number of renal tube-casts as well as albumin in the urine, it is almost certain that there is an inflammatory lesion of the kidney. The next step in the diagnosis is to decide by microscopical examination whether pus is present also; in other words, the cases may be subdivided into two main sub-groups, namely: (A) *Albuminuria with renal tube-casts without obvious pus*; and (B) *Albuminuria with renal tube-casts and obvious pus*. There are border-line cases in which leucocytes are present in excess, and yet not in sufficient numbers to constitute pus; other points about such a case will generally lead one to decide whether it comes

in the apyuric or in the pyuric group. The differential diagnosis of the latter is discussed under PYURIA (p. 715), so that it only remains here to discuss : -

A. THE DIFFERENTIAL DIAGNOSIS OF ALBUMINURIA WITH TUBE-CASTS WITHOUT OBVIOUS PUS.

The causes of this condition may be classified as follows : -

1. The Various Forms of Bright's Disease:—

- a.* A primary acute nephritis.
- b.* An acute exacerbation upon an underlying chronic nephritis.
- c.* Chronic nephritis of young people : (i) Arising out of a known attack of acute nephritis ; (ii) Arising without any known previous attack of acute nephritis.
- d.* Chronic nephritis of old people : (i) Cirrhosis of the kidneys ; (ii) Arteriosclerosis.
- e.* Cystic disease of the kidneys.

2. Nephritis of Pregnancy.

3. Chronic Ascending Nephritis, leading to scarred contracted kidneys, the result of -

a. Obstruction to urine outflow by :—

- i. Urethral stenosis.
- ii. Enlarged prostate.
- iii. Displacement of the womb.
- iv. Fibromyoma, ovarian cyst, or other pelvic tumour.
- v. Pregnancies.
- vi. Undue mobility of the kidney and kinking of the ureter.
- vii. Rarities, such as abdominal aneurysm obstructing a ureter.

b. Irritation ascending from the pelvis of the kidney, the result especially of calculus, but also sometimes of chronic tuberculous lesions.

4. Lardaceous Disease of the Kidneys.

5. Infarction of the Kidneys, especially when the result of embolism in case of fungating endocarditis ; but also due to thrombosis, as in some blood diseases.

6. Thrombosis of the inferior vena cava involving the renal veins.

7. New Growth of the Kidney, some cases.

In many cases the diagnosis soon becomes obvious, but in some there may be great difficulty. The two following may serve to illustrate how such difficulties may arise :—

A patient of middle age, who had not been strong for a long time, began to suffer from œdema of the ankles, which increased rapidly and spread to her legs, thighs, genital organs, and back. Within a few days her abdomen began to swell, and she began to pass very little water, the colour of blood. Upon examination the urine had a sp. gr. of 1030, was loaded with albumin and blood, and microscopically there was an abundance of red corpuscles, renal epithelial cells, leucocytes, and epithelial, fatty, granular, and blood casts, without pus, crystals, or bacteria. It seemed almost obvious that she must be suffering from acute Bright's disease ; but there was no œdema of the eyelids, and there was definite enlargement of the left supraclavicular lymphatic gland ; the discovery of the latter led to a very careful examination for malignant disease ; and a latent and quite unsuspected carcinoma of the rectum was found. The diagnosis was carcinoma recti, secondary deposits in the retroperitoneal glands, obstruction and thrombosis of the inferior vena cava and of the renal veins, with consequent albuminuria, hæmaturia, and renal tube-casts from asphyxial nephritis, simulating acute Bright's disease.

Another case was that of a girl of 16, suffering from increasing anæmia, shortness of breath, œdema of her ankles and face, and slight pyrexia. The heart was a little enlarged, and there were soft systolic bruits that were regarded as secondary to the anæmia. The urine contained blood and albumin, with renal epithelial cells and tube-casts in abundance. Ascites developed, with increasing general œdema ; there were also retinal hæmorrhages and neuro-retinitis. The diagnosis of acute nephritis, however, was only in small degree correct ; for she was really suffering from malignant endocarditis of a subacute type, the nephritis being due to infected emboli of the kidney producing inflammatory changes around multiple renal infarcts.

These cases will serve to show how it may be impossible to arrive at a correct diagnosis except by thorough examination of all the systems, by watching the case carefully, and by repeating the full systemic examination at intervals. We will now deal with the

If there is **New Growth** in a kidney the number of renal tube-casts is likely to be small ; sooner or later a microscopic fragment of new growth may be detected in the centrifugalized urinary deposit. Albuminuria will not be extreme unless the renal veins and the inferior vena cava become involved (*Fig.* 683, p. 909), the same applying also to the œdema of the legs and trunk ; hæmaturia is likely to occur at intervals, the attacks being separated by many weeks sometimes, and being relatively painless ; there may be an increasing renal tumour ; cystoscopic examination may show blood-stained urine (*Fig.* 293, p. 354) coming from one ureter only ; and finally, when suspicion of new growth has been aroused, operation may be indicated and the diagnosis confirmed thereby.

Thrombosis of the Renal Veins and Inferior Vena Cava has been referred to above as a condition that may simulate acute nephritis. Points to lay stress on in arriving at the diagnosis are : (1) To make a very careful and systematic examination, including that of rectum and vagina, in order not to miss anything, such as some latent growth whose secondary deposits are obstructing the veins ; (2) To inquire carefully into the history — many cases of inferior vena cava thrombosis are due to extension upwards from iliac or saphenous clots, in which case there will nearly always have been swelling of one leg only to start with, followed later by extension to the back and to the other leg ; (3) To note that although the œdema of the legs and back may be extreme, there is a definite upper level to it and no swelling of the eyelids or scalp ; and (4) To note that if there are any distended or varicose veins upon the abdominal wall (*see* VEINS, VARICOSE ABDOMINAL, *Fig.* 682, p. 908), the current in them has become reversed to being from below upwards instead of from above downwards.

Infarction of the Kidneys may be either embolic or thrombotic. The commonest cause of embolic renal infarction is fungating endocarditis. Each embolus gives rise to the sudden appearance of blood in the urine which may have contained none previously, or to increase in any existent hæmaturia ; there may or may not have been a sudden pain in the back at the same time. Around each infarct acute nephritis develops, so that in some cases all the characters of the latter malady may be superposed upon those of the fungating endocarditis. If the patient is already known to have heart disease the diagnosis is easy enough ; the difficulties arise in cases in which, notwithstanding the endocarditis, there is no bruit. If fungating endocarditis is suspected, the points that confirm the diagnosis are those mentioned on p. 46.

Thrombotic infarcts are less severe in their effects ; they may produce no hæmaturia at all, and the albuminuria may be slight, and unaccompanied by tube-casts. They generally arise in cachectic conditions, or in blood diseases such as leukaemia or pernicious anæmia, in which case the diagnosis will be arrived at on other grounds, albuminuria not being the prominent feature of the case.

Lardaceous Disease of the Kidneys used to be common in the days of septic surgery, but it is uncommon now. It is a risky diagnosis to make, therefore, unless there be an obvious cause for it, such as long-standing suppuration in association with a spinal, hip-joint, or empyema sinus, bronchiectasis, phthisis with cavitation, ulcerative colitis, or the like ; or clear evidence of tertiary syphilis with cachexia. There is nothing characteristic about the urine. In the earlier stages there may be but a trace of albumin in an otherwise normal urine ; later, the albumin increases and it may reach very large amounts, such as 20 parts per 1000, casts being very few in proportion, the total amount of urine increased, its colour pale, and its sp. gr. low — 1005 to 1012 ; later still, possibly as the result of superposed nephritis, the amount of urine falls until only a few ounces may be passed each day, of high colour and sp. gr. 1020 to 1035, loaded with albumin, and now containing hyaline, waxy, granular, fatty, and epithelial casts. Lardaceous casts may or may not occur, but they are not diagnostic, for they have also been found in cases of nephritis without lardaceous disease. Indeed, the diagnosis of lardaceous kidney resolves itself into one of guesswork in a case in which there has been prolonged suppuration or severe syphilis to give rise to it, and in which there may be smooth firm enlargement of the liver, moderate enlargement of the spleen, and more or less severe diarrhœa, to indicate corresponding lardaceous change in the other organs that are generally affected at the same time as the kidneys ; whilst at the same time the facies may be that of a progressive pallor of primrose-yellow tint almost like that of pernicious anæmia, but with a blood-count corresponding to secondary anæmia with low colour index.

Chronic Ascending Nephritis arises from precisely the same causes as acute ascending nephritis or surgical kidney, and probably results from recurrent focal inflammations which heal, with the result that, in the course of months or years, the kidneys are converted into a mass of irregular fibrotic scars which together produce the same local and general changes and effects as are found in cases of ordinary red granular contracted kidney. It is important to bear in mind that any cause of prolonged obstruction to the urine outflow may cause granular kidney with albuminuria, without pus but with casts, in a pale abundant urine of low specific gravity. The diagnosis will generally be obvious when the obstruction is due to urethral stricture; it is more apt to be overlooked in other cases, though if one bears in mind the causes mentioned in the list above, the methods of diagnosis will generally be clear. One would only mention in particular that uterine tumours or displacements are a very common cause for slight albuminuria and a few renal tube-casts in women; and that in men of sixty and over enlargement of the prostate causes a precisely similar condition long before there is any definite pyuria.

Pregnancy Nephritis is sometimes spoken of as though it were altogether different from nephritis of the Bright's disease type in general. I do not subscribe to this view. I hold that Bright's disease has many different causes and many different types. It may be due to scarlet fever, in which case it is very possibly streptococcal; it may be due to pneumonia or empyema, in which cases it may be pneumococcal; it may be due to various other micro-organisms; it occurs in some cases of cholera, and in severe secondary syphilis; it is frequent in malaria, especially the quartan type; it may be due to chemical substances such as turpentine, cantharides, or oxalic acid; it very often seems to come on from no known cause at all, though in such cases there must be a microbial or other cause that is not discovered, though it should be looked for in relationship to septic tonsils, recurrent boils of the skin, pyorrhæa alveolaris, intestinal toxæmia, vaginal discharges or infection of the cervix, uterus, or uterine appendages, chronic appendicitis, chronic otitis media, post-nasal catarrh, persistent purulent bronchitis, bronchiectasis, or indeed any chronic microbial infection from which toxic absorption may lead to damage of parenchymatous organs such as the kidneys. In all such cases an extensive bacteriological investigation of all the orifices is called for, though it may still be difficult to decide whether the organisms thus discovered are merely accidental or really causative. It may be due to pregnancy, in which case it is ascribed to unknown toxins. In all these cases the types of reaction on the part of the kidney are similar, and one can only regard pregnancy nephritis as a variety of non-suppurative nephritis in general. Very likely it is only a matter of degree whether it is non-suppurative or merges into the type in which there is pyuria as well as albuminuria—pyelitis of pregnancy. Pregnancy may cause a primary acute nephritis, which may recover either completely, or but partially and persist as chronic nephritis; or may seem to recover when in reality it is merely latent, or even slowly and insidiously progressive; it may produce what seems to be a primary acute nephritis which is really but an exacerbation superposed upon a chronic nephritis that has been unsuspected; and very possibly it may produce nephritic changes which are not associated with definite symptoms at the time, but which ultimately result in what is spoken of as chronic interstitial nephritis. When, therefore, albuminuria with renal tube-casts, but without pyuria, occurs during pregnancy, it matters little what name is given to the condition, provided it is realized that just the same difficulties offer themselves here as in Bright's disease in general, in arriving at a conclusion as to whether the renal lesion is acute, chronic, or acute on chronic.

Various Forms of Bright's Disease.—Of all these, the hardest to diagnose with certainty is *primary acute nephritis* in the adult. The majority of adult cases that are labelled acute Bright's disease are really suffering, not from primary acute nephritis, but from an acute exacerbation upon the top of already existent but possibly latent chronic nephritis. The difficulty is to arrive at the diagnosis between these two, particularly since many of the points mentioned in text-books as occurring in acute nephritis are really due, not to the acute attack, but to the subacute or chronic renal lesion which has, until then, been unsuspected.

The best examples of primary acute nephritis are to be seen in cases that are already under observation for some other disease, notably scarlet fever, lobar pneumonia, or acute influenza. Sometimes the onset of the nephritis is indicated by general œdema, especially

of the eyelids and face, ankles, genital organs, and loins; but it cannot be insisted upon too strongly that œdema is not essential, many cases of acute nephritis having no œdema at all, especially if the patient is already in bed when the kidney inflammation begins, as in scarlatina cases. If the urine were not examined the renal lesion would often escape recognition altogether; and there can be no doubt that many cases of primary acute nephritis do escape recognition in this way, coming under observation later when they present symptoms of chronic nephritis, or an acute exacerbation on chronic nephritis.

The essential point in the diagnosis is urine examination. According to the severity of the nephritis there will be more or less diminution in the total daily quantity: it is common for less than 20 oz. to be passed in the twenty-four hours, and often the amount falls to 10 oz., 5 oz., or even to none at all for a while. The specific gravity is raised to 1025, 1030, or even to 1035, but rarely to 1040. The reaction is generally acid at first, but it soon becomes alkaline on standing. The colour is extremely variable, according as little or much blood is present: sometimes it is almost normal or merely that of a concentrated urine; more often there is some tinging with blood, varying from bright red to brownish, brown, brown-black, or to that peculiar tint which is described as smoky. There is a general cloudiness of the specimen, and on standing it deposits a heavy sediment which often has a dark brownish tint owing to the phosphates carrying the blood pigment with them. Microscopically the centrifugalized deposit consists partly of amorphous debris due to earthy phosphates, and to the disintegration of cells and tube-casts; and one expects to find an abundance of red corpuscles, renal epithelial cells, variable numbers of epithelial, fatty, granular, hyaline, and blood casts, an excess of leucocytes, an occasional crystal of calcium oxalate or uric acid, and irregular granular masses which are not definitely tube-casts. It is noteworthy, however, that in the very acute stages there may be no tube-casts, though shed renal epithelial cells are abundant: in such a case tube-casts will show themselves in a few days. It is important that each specimen should be examined as fresh as possible, owing to the tendency of casts and cells to disintegrate on standing. In addition to red corpuscles there is often much free hæmoglobin: the tincture of guaiacum test will be positive, and the spectroscope will show the bands of oxyhæmoglobin—or of methæmoglobin (*Figs. 17, 22*). Coagulable protein is generally present in abundance, the proportions of globulin and albumin varying greatly, but together amounting to anything between 2 and 20 parts per thousand—often about 15 parts per thousand at first, rapidly dropping to less after the first few days of treatment, until at the end of from a fortnight to a month it may be 1 part per thousand or less, or even absent altogether. In a few cases, however, there is very little coagulable protein but an abundance of albumose, so that the boiling test gives but a faint cloud, whilst the nitric acid test yields a dense white ring, soluble on warming, to reappear on cooling. There is generally an excess of nucleo-protein also. The urea, chlorides, and phosphates all fall below the normal totals, though their percentages may be increased if the urine is concentrated.

With this condition of urine there will be little doubt as to the presence of acute nephritis: the only question then is whether it is primary, or an exacerbation upon chronic nephritis. The former is probable if it is known that the urine was free from albumin up to the time of the attack, if the patient is known to have suffered recently from scarlet fever, pneumonia, diphtheria, secondary syphilis, severe influenza, or some other similar fever: if the heart is of normal size and its sounds are natural, the blood-pressure natural, and the retina healthy. It may be that the patient himself may have been exposed to scarlatinal infection, and without having had the rash may develop nephritis: the association of peeling of the skin, or recent sore throat with enlarged glands in the neck, or otitis media, might suggest the diagnosis in these mild cases of scarlatina, though sometimes acute nephritis in a child may be the sole evidence of the disease. The course of the malady will also assist the diagnosis; the albuminuria of primary acute nephritis may clear up entirely in from a fortnight to six weeks, though in unfavourable cases it persists and chronic nephritis develops out of the acute. If, on the other hand, it is found that, in a case of apparently recent acute nephritis, with general œdema, hæmaturia, and the other urinary changes described above, there is cardiac hypertrophy, with a prolonged lumpy first sound at the impulse, a ringing aortic second sound, a blood-pressure of more than 180 mm. Hg, and possibly albuminuric retinitis, the probability is that the acute

nephritis is not primary, but an acute exacerbation of an unsuspected chronic nephritis. There is often a history of former scarlet fever or of syphilis in such cases ; the patients may be of any age, from childhood to past middle life. If the patient survives, one or other of two conditions usually results : either the albuminuria, the scanty urine, and the tube-casts persist, whilst the patient remains waterlogged until the end comes in a few weeks or months, or else the acute exacerbation subsides and the clinical characters of chronic nephritis remain.

Some of these cases, but by no means all of them, are examples of primary acute nephritis, persisting and becoming chronic. It must, however, always be very difficult, and indeed almost a matter of opinion in many cases, to decide whether a patient is suffering

from a chronic nephritis which is the result of a primary acute nephritis that has not cleared up, or from a chronic nephritis which was present but unrecognized before an acute exacerbation drew attention to it ; my own view is that many cases in which adults seem to develop acute nephritis from no more definite cause than exposure to damp or cold, are really examples of acute on chronic, and not of primary acute, Bright's disease. The albuminuria in these cases does not clear up, and it is a mistake to restrict the diet or the daily occupation after the acute exacerbation has subsided. In spite of the persistence of albuminuria, these patients do best if they are given iron and allowed to go about their ordinary avocations ; they have diseased kidneys, and they will not live many years, but there is no need to adopt treatment which constantly reminds them of the fact.

As the acute exacerbation subsides, the amount of urine rises rapidly to 60 or 70 oz. or more per diem, and remains increased even after all œdema has passed away ; the specific gravity falls to 1012, 1010, or 1008 ; the albumin persists to the extent of anything between 0·5 and 8 parts per thousand ; blood is absent, though an occasional red corpuscle may be seen under the microscope ; and there are moderate numbers of hyaline, granular, or even fatty casts, with an occasional renal epithelial cell.

It happens not infrequently that a young patient suffering from *chronic nephritis* comes under observation for shortness of breath, palpitations, anæmia, or for inflammation of one or other of the serous membranes, without ever having had any symptoms of acute nephritis at all. The kidneys that would be found in such cases differ from the granular contracted kidneys of older people in that they are pale instead of red. They are pale granular contracted kidneys, precisely similar to those which may result from a long antecedent acute nephritis that has not entirely cleared up. When they develop without any known preceding attack of acute nephritis they have been referred to as Rose-Bradford kidneys. It is by no means impossible that they are really the result of a preceding acute nephritis which escaped recognition because there was no œdema to attract attention to the need for urine examination. The patient may be of any age, though generally between five and thirty-five. There may be no sign of anything wrong until acute uræmia, with convulsions, leads to rapid death. On the other hand, in a typical case, in addition to the urine changes mentioned above, one expects to find some of the following symptoms or signs : a great increase in the size of the left ventricle, as evidenced by displacement of the impulse downwards and outwards, even into the sixth left intercostal space below or outside the left nipple, with increase of the precordial impairment of resonance outwards to the left without corresponding increase upwards or to the right ; a ringing second sound in the second right intercostal space close to the sternum, and a prolongation of the first sound at the impulse, or its replacement by a localized blowing systolic bruit ; more or less anæmia, sometimes very considerable and of the chlorotic type ; a maximum systolic blood-pressure, of 175 mm. Hg, or more, sometimes over 300 mm. Hg, even when the pulse feels comparatively soft to the finger ; albuminuric retinitis ; a tendency to hæmorrhages, especially to epistaxis ; headache ; insomnia ; breathlessness on exertion ; and inability to work with the usual energy, either mentally or physically. A certain number of such cases occur in quite young children, and in some of these the cause is congenital syphilis, and a Wassermann reaction should be taken to test this point ; some such cases are the subject of INFANTILISM (p. 234).

The *chronic nephritis of old people* is diagnosed more often than it exists, if one understands by it the disease associated with small red granular contracted kidneys. On the other hand, the kidneys of most old people exhibit a certain amount of interstitial fibrosis, with occasional retention cysts and some granularity of the surface when the capsules are stripped off, without there being any material diminution in their size. Where senile changes that are almost normal end and chronic interstitial nephritis begins is difficult to determine. The same applies to *arteriosclerosis* and the renal changes associated with this. Some regard arteriosclerosis and chronic interstitial nephritis as essentially different maladies ; others regard the arterial as secondary to the renal changes ; others hold that arteriosclerosis leads to a variety of red granular kidney that is not the same as the red granular contracted kidney of chronic interstitial nephritis ; whilst others again favour what seems a likely view, namely that arteriosclerosis and sclerosis of the kidneys both have common causes, and that it is more or less an accident whether the patient, on post-mortem examination, presents more arterial or more renal changes, or about the same degree of both. During life the differential diagnosis between them is sometimes impossible. In either case there will be a hypertrophied left ventricle, a loud lumpy first sound, or a blowing systolic bruit, at the impulse, a markedly accentuated aortic second sound, a systolic blood-pressure somewhere between 180 and 320 mm. Hg, with a tendency to shortness of breath ; giddiness, especially on sudden change of posture ; ringing in the ears ; difficulty in concentration of mind ; and very possibly cardiac symptoms, varying from a mere consciousness of the existence of the heart, to precordial pain of varying severity, or even extreme heart failure with œdema of the legs, ascites, nutmeg liver, orthopnoea, and pulmonary congestion. In the latter case the great difficulty will be to decide whether the heart failure is due to primary renal or arterial, primary cardiac, or to

primary pulmonary disease, and the only sure methods of deciding that there is a renal lesion are : the discovery of more than an occasional granular and hyaline tube-cast in the urine ; the detection of albuminuric retinal changes ; and instrumental determination that the blood-pressure is much raised. Sometimes inflammation of one of the serous membranes is the first symptom : subacute or chronic peritonitis with ascites ; pericarditis ; or pleuritic effusion. On the other hand, the patient may seem to have been in robust health until the nature of the case is suggested by a sudden apoplectic seizure due to cerebral hemorrhage. In yet another group of cases the malady is discovered accidentally as the result of examination for life insurance. It is not very uncommon to find glycosuria as well as albuminuria, the sugar occurring in a urine of normal specific gravity without any associated acetone or diacetic acid. The degree of albuminuria is very variable : when there are signs of cardiac failure there may be oliguria with much albumin and not a very large number of casts ; when there is no heart failure there is generally polyuria, the patient having to rise several times in the night, passing from 60 to 120 oz. of pale urine in twenty-four hours, of sp. gr. 1008 to 1012, often containing only a trace of albumin, and even that not constantly ; there are intermediate cases in which the amount of albumin varies from 0.25 to 4 or 5 parts per thousand. Upon the whole one may say that, if the increased albuminuria due to heart failure on the one hand, or to a super-added acute attack of nephritis on the other, can be excluded, the more the disease approaches the type of red granular contracted kidney, the more likely is the albumin to be small in amount and intermittent ; whilst the more the disease approaches in type to pale granular contracted kidneys the greater will be the amount of albumin, if any is present at all. There will be tube-casts, chiefly granular and hyaline, most numerous with pale granular contracted kidneys, fewest with arteriosclerosis, and intermediate in numbers with red granular contracted kidneys. It need scarcely be added that the absence of albuminuria does not exclude arteriosclerosis : but we are here dealing only with cases in which albuminuria occurs.

Cystic Disease of the Kidneys is found in three entirely different types of patients, namely, (1) the newborn, (2) the young, and (3) the elderly. In the newborn the main symptom is abdominal distention, which may be so extreme as to have caused difficulty in delivery : the bilateral cystic tumours can be felt, and the diagnosis in such cases is not difficult. Minor degrees escape detection at birth, and it may be that several years elapse before the diagnosis is arrived at as the result of finding bilateral uneven renal tumours associated with the passage of abundant pale urine of low specific gravity containing traces of albumin, a few granular and hyaline tube-casts, and an occasional red corpuscle. Sometimes a sudden and severe attack of hæmaturia is the first symptom. The discovery of bilateral irregular renal tumours is the clinching point in the diagnosis. In at least one case they were so large as to meet in the middle line, so that a loop of intestine that had passed between and behind them could not get out again, and the patient came under observation for acute intestinal obstruction. The third type of cystic disease of the kidneys occurs in old persons, and is but a variety of chronic interstitial nephritis in which the agglomeration of retention cysts has reached an extreme degree : the enlargement of the kidneys is then much less than it is in young persons, where the lesion is probably congenital ; the symptoms and urinary changes are precisely similar to those already described in cases of red granular contracted kidneys.

B. ALBUMINURIA WITH RENAL TUBE-CASTS AND WITH PUS.

When pus is present in the urine along with albumin and renal tube-casts the differential diagnosis resolves itself into that of pyuria that is partly or wholly of renal origin (see PYURIA, p. 715). It only remains to add : first, that it is not sufficient to rely upon the naked-eye characters of the urine, or upon chemical tests, in excluding minor degrees of pyuria : microscopical examination of the centrifugalized deposit is essential, especially in the detection of acute pyelitis and pyelonephritis the result of coli-bacilluria in children, pregnant women, and others (p. 88) ; secondly, that the amount of albumin actually due to pus itself is small, so that if there is any measurable quantity of albumin present it indicates that the kidneys are themselves affected, this being further confirmed when casts are also found ; and thirdly, that blood, like pus, is in itself responsible for relatively little albumin, so that when there is considerable

albuminuria associated with blood there is strong ground for believing that the albumin is by no means all due to the blood. The presence of very small quantities of blood does not assist the differential diagnosis of the cause of albuminuria so much as might be expected; much blood indicates that the cause is due to one or other of the conditions discussed under HÆMATURIA (p. 317).

II.—ALBUMINURIA WITHOUT TUBE-CASTS.

Turning now to albuminuria without tube-casts, one would emphasize the fact that more than one microscopical examination may be required, for if the urine is alkaline, or has stood for any length of time, casts, originally present, may have become unrecognizable; besides which, even with definite nephritis, there may be very few casts at one time, many at another. This applies particularly to the very acute cases on the one hand and the very chronic on the other. Assuming that not more than a very occasional cast is found, the chief conclusion that can generally be drawn is that the albuminuria is not indicative of organic renal disease. The cases may then be subdivided into: (1) *Those in which the urine presents some other definite abnormality besides albuminuria*, especially (a) pyuria, (b) hæmaturia, (c) hæmoglobinuria, or (d) glycosuria; (2) *Those in which, were the albumin removed, the urine would be normal*.

1. These cases need not be discussed further here; the differential diagnosis will be found under PYURIA, HÆMATURIA, HÆMOGLOBINURIA, and GLYCOSURIA respectively.

2. These are clinically of importance in that, until the absence of casts has been determined, the absence of organic renal changes cannot be concluded. Even when casts are absent, a trace or a small amount of albumin may be the first evidence in elderly persons of enlargement of the prostate, chronic interstitial nephritis, or arteriosclerosis; or, in younger persons, of renal calculus, tubercle, or growth, or of chronic ascending nephritis, the result of such things as former gonorrhœa, repeated pregnancies, uterine prolapse or other displacement, chronic vesical catarrh, or urethral stricture. Slight albuminuria often occurs in the latter half of life without any clinical significance attaching to it; renal disease may be suspected, feared, or even diagnosed, and yet the patient survives for many years without any other renal symptoms developing, dying finally of something else. It is always difficult to assess the importance of slight albuminuria, without tube-casts, in elderly persons who present no other evidence of disease such as raised blood-pressure, hypertrophied heart, or retinitis.

The following are a number of other conditions which may cause slight degrees of albuminuria without tube-casts, but which are obvious, or else diagnosed by other signs that are discussed elsewhere: burns, scalds, chronic alcoholism, cirrhosis of the liver, diabetes mellitus, exophthalmic goitre, myxœdema, gout, lead-poisoning, mumps, secondary syphilis, morphinism, mercurialism, vasomotor neuroses such as Raynaud's disease, neuroneurotic œdema, obstruction to the vena cava inferior by thrombosis or by external pressure, the pressure of considerable ascites, ovarian cysts, or solid tumours, pernicious œmia, Hodgkin's disease or lymphadenoma, lymphosarcoma, lymphatic or splenomedullary leukaemia, splenic anæmia, pemphigus, phosphorus poisoning, chronic arsenical poisoning, pregnancy, severe anæmia the result of syphilitic, malarial, malignant, tuberculous, or plithalic cachexia, ankylostomiasis, or infection with other parasites such as *Bothriocephalus latus* or *Trichina spiralis*.

There remain three other groups of conditions in which albuminuria and its differential diagnosis are often important, and these are: (i) *Febrile conditions*; (ii) *Heart failure conditions*; and (iii) so-called '*Physiological*' albuminuria of adolescence.

i. **Febrile Conditions.**—In nearly every fever there is some cloudy swelling of the parenchyma of various viscera, especially the kidneys; consequently most fevers may sometimes be associated with albuminuria, and, broadly speaking, the higher the patient's temperature the greater is the liability to it. The amount of albumin present is generally not great. We need not enumerate all the various fevers in this connection. Suffice it to say that albuminuria is relatively common in scarlatina, diphtheria, tonsillitis, variola, erysipelas, pyrexial phthisis, cholera, dysentery, Weil's disease, trench fever, severe malaria, and yellow fever; not so common in lobar pneumonia, bronchopneumonia, typhoid fever, and empyema; and relatively uncommon in other febrile conditions, such as acute

rheumatism, influenza, meningitis, measles, German measles, and so on. The albuminuria may, of course, be already present in a person who develops an intercurrent fever; the diagnosis then depends upon considerations mentioned above.

If, on the other hand, the albuminuria is known to have developed coincidently with the febrile illness, the chief point to decide will be whether it indicates actual nephritis or not. Many consider there is an essential difference between 'febrile albuminuria' and actual nephritis. This may or may not be so, but it is extremely difficult to be sure of the distinction clinically. It may be urged that—to take scarlet fever as an example—the albuminuria of the first few days is 'febrile', whilst that of the second or third week is 'nephritic'. As a matter of fact, in not a few cases in which death has occurred in the first week the 'febrile' albuminuria has been associated with large mottled acute nephritic kidneys, even where there has been no oedema, no hamaturia, and no very large numbers of renal tube-casts. Probably there are all degrees of acute nephritis, from very slight and transient, to very severe and fatal; and it is a mistake to try and make a distinction in kind. The great majority of cases of albuminuria during fever recover completely; some seem to recover, but come under observation years later with pale granular contracted kidneys; others die during the acute attack. The degree of albuminuria is not a direct measure of the renal changes unless the amount of albumin is large; a small amount of albumin does not necessarily indicate trivial nephritis. Absence of oedema is the rule. Microscopical examination of the centrifugalized urinary deposit is essential: the more the renal epithelial cells, red corpuscles, leucocytes, and various renal tube-casts, the more conclusively can some degree of actual nephritis be diagnosed.

In pneumonia, albuminuria has become much less frequent since blistering with cantharides has gone out of fashion in treating this disease.

ii. Heart-failure Conditions.—The right side of the heart may fail owing to many different causes, which may be arranged under four main headings, as follows: (a) Valvular disease; (b) Obstructive lung affections; (c) Myocardial affections; (d) Granular kidneys and other high blood-pressure conditions. Each of these main headings has many sub-headings (see *Dyspnoea*, p. 246). Any one of them may result in albuminuria, though the amount of the latter is extremely variable, some cases of severe heart failure exhibiting no albuminuria at all, whilst others may have as much as 10 parts per 1000, or more.

The first step in the differential diagnosis is to *exclude primary renal conditions* by negative microscopical examination of the centrifugalized urine deposit for casts, examination of the retina, and determination of the blood-pressure. Curiously, even with feeble irregular pulses, such as are found in panting cases of mitral stenosis, the blood-pressure is considerably higher than normal, doubtless owing to partial asphyxia: so that merely finding a systolic blood-pressure of 150 or 160 mm. Hg is no proof of granular kidney or arteriosclerosis; sometimes, however, the reading is as high as 200, 250, 300, or even 320 mm. Hg, and then the diagnosis of one or other of the latter is almost certain.

If renal and arteriosclerotic conditions can be excluded, the diagnosis lies between the other three main groups. The cardiac bruits, the history of growing pains, chorea, or acute rheumatism, the youth of the patient, the family history of heart disease or rheumatic fever, the association of other rheumatic affections such as recurrent tonsillitis, subcutaneous nodules, or erythema, will often serve to point to *primary valvular disease*; in older patients, especially men between forty and fifty, there may be aortic regurgitation and a history of syphilis and not of acute rheumatism. In severe heart failure in children under puberty, the result of mechanical difficulty with the circulation, an *adherent pericardium* is generally found, and clinically the heart is large out of proportion to the general physical signs.

When there is a definite history of recurrent winter cough in an elderly person, with a hyper-resonant and over-expanded chest, the likelihood of *emphysema and bronchitis* will at once suggest itself. Similarly *fibroid lung*, or fibroid lung and *bronchiectasis*, as a cause of heart failure and albuminuria, only needs mentioning, the diagnosis generally being obvious from the physical signs, the clubbed fingers, and in the bronchiectatic cases the abundant intermittent, and frequently foul, expectoration.

Myocardial affections, such as fibroid, fatty, or primary alcoholic heart, are generally diagnosed by guessing at them when other causes of heart failure can be excluded. The patients are generally middle-aged, shortness of breath on exertion, precordial pain and

even angina pectoris occupying a prominent position amongst their cardiac symptoms : there may or may not be a high blood-pressure, the albuminuria is not associated with renal tube-casts, there is often no cardiac bruit, or at most a more or less localized blowing systolic bruit at the impulse : at the same time the heart is clearly enlarged, and it may be beating rapidly and irregularly : there may be a history of syphilis or of chronic alcoholism : the patient may be very stout in the fatty, though generally not so in the fibroid, cases. There may be a history either of an extremely sedentary life upon the one hand, or of over-use of the heart by strenuous hard physical work—as a blacksmith, an athlete, and so forth—on the other. Electrocardiographic tracings may be required in determining the nature of the heart lesion (see PULSE, IRREGULAR, p. 663 : etc.).

Needless to say, the exact nature of the cardiac lesion remains obscure or uncertain in many of these cases, many a patient who really has mitral stenosis being regarded during life as suffering from chronic bronchitis and emphysema, and so on.

iii. '**Physiological' Albuminuria.**—Finally, we come to the albuminuria of apparently healthy males and females between the ages of fifteen and thirty. The condition was little known until medical examinations at schools, or for life insurance, or for the services became common. It has received a number of names, of which the following are some : 'accidental,' 'essential,' 'postural,' 'cyclic,' 'orthostatic,' 'intermittent,' 'physiological,' 'functional,' 'orthotic' albuminuria, Pavy's disease, albuminuria 'of adolescence' or 'of puberty.' It derives its chief importance from the fact that young males who suffer from it may be rejected for life insurance or for the services, from the fear that they have some form of nephritis. A similar condition occurs in females of a similar age, but it is detected less often than in males because one has less occasion to examine the urines of healthy girls than is the case with boys and youths. Collier and others have thrown much light upon the nature of the affection by their investigations upon the urines of rowing men. It is found that the urine passed just before a boat-race being free from albumin, that voided immediately after is generally loaded with it. A few hours later this albuminuria is gone again. Now university oarsmen are, upon the whole, long lived, hence this recurrent albuminuria cannot matter in them : and the same applies to the albuminuria of many adolescents. A prominent feature of such a case is that the urine first voided in the morning is quite normal, whilst that passed later in the day may contain anything from a trace to 5 parts per thousand of albumin : the more the youth has exerted himself physically by walking or otherwise, and the more he has exposed himself to cold, for instance during a train journey to the city on a winter's day, or in a cold bath, the greater is the liability to this unimportant but possibly alarming albuminuria. Some youths may pass albumin for days together before an interval of freedom from it occurs. Sometimes they appear to be in robust health, sometimes they look a little pale, as though they had been overworking at an indoor occupation : they may be nervous, but often they are not. A natural nocturnal emission is supposed to predispose to albuminuria next day : so also is a diet which includes eggs, especially raw eggs. The point is that these individuals have to be differentiated from sufferers from Bright's disease. The method of diagnosis is as follows : a complete routine examination is carried out, and no obvious affection of the heart or other viscera is detected : the blood-pressure is normal ; the albumin having been discovered, the patient is directed to supply a series of samples, at intervals of a few days, and preferably passed immediately after rising in the morning. If all samples contain albumin it will be very difficult to exclude organic disease ; if some contain albumin in abundance, however, and others none at all, the presumption will be that it is 'functional' ; before being finally satisfied, however, it is important that a careful microscopical examination of the centrifugalized deposit from a specimen containing albumin should be made, no casts or other abnormal constituents being found. The administration of calcium chloride or calcium lactate is said to diminish the tendency to this form of albuminuria. In an adolescent male who has no symptoms, albuminuria discovered accidentally, present after exertion or after exposure to cold but absent after rest in bed, and when present not associated with renal tube-casts or with signs of arterial, cardiac, or other disease that should be detected by physical examination, is almost certainly 'physiological,' needing no treatment and not indicative of any underlying disease. The chief difficulty is to be sure that the intermittent albuminuria is not the result of tuberculosis of the kidney in an early stage ; with this, the degree

of albuminuria is seldom great, whereas with physiological albuminuria the amount of albumin may be quite large at one time of the day, in marked contrast to its entire absence the first thing in the morning. Another condition which may be responsible for intermittent albuminuria, lessening with rest, increasing with exercise, is calculous disease of a kidney; the diagnosis will be difficult until colic or hæmaturia draws closer attention to the nature of the case, or unless radiography is made part of a routine examination.

RENAL EFFICIENCY TESTS.

It is often important to decide whether, in association with albuminuria, the renal changes are grave or slight; and various tests of renal efficiency have been devised. Some of these depend upon injecting subcutaneously substances which give a decided blue or red coloration to the urine which is excreted subsequently. These are complex, and difficult of use and interpretation except at the hands of experts. Three simpler tests are: (1) *The urea concentration test*; (2) *The diastatic test*; and (3) *The test by estimation of the urea in the blood*.

The urea concentration test consists in getting the patient to empty his bladder completely at a suitable hour in the morning, no breakfast having been taken and no tea or other fluid drunk. He is then given, by the mouth, a solution of 15 grm. of urea in 100 c.c. of water; at the end of one hour, and again at the end of two hours, he voids any urine that has collected in the bladder, and the percentage of urea in each of these specimens is estimated by the sodium hypobromite method. If the kidneys are healthy, the percentage of urea in each specimen will be 2 per cent or over; if they are diseased, but still efficient, the urea percentage will still be 2 or more in either or both; but if the urea percentage is below 2 the kidneys are inefficient. It is a question, not of the total amount of urea excreted in the time, but of the percentage of urea in the liquid eliminated by the kidneys after 15 grm. have been given by the mouth on an empty stomach.

The diastatic test consists in estimating the diastatic content of the urine, and, though it is not essential, it is better to have a sample from the urine collected for twenty-four hours, because the diastatic content varies at different periods of the day.

The solutions required are: (1) A 0.1 per cent solution of starch prepared by boiling 0.1 grm. of soluble starch in a small amount of water and then diluting to 100 c.c.; (2) A 0.9 per cent solution of sodium chloride in distilled water; (3) A decinormal solution of iodine. To five numbered test-tubes are added:—

	URINE	SALINE SOLUTION	STARCH SOLUTION
To tube 1	1.0 c.c.	0.0 c.c.	2 c.c.
" " 2	0.6 c.c.	0.4 c.c.	2 c.c.
" " 3	0.3 c.c.	0.7 c.c.	2 c.c.
" " 4	0.2 c.c.	0.8 c.c.	2 c.c.
" " 5	0.1 c.c.	0.9 c.c.	2 c.c.

The tubes are then shaken quickly and put into an incubator or water-bath at a temperature of 37° C. for exactly thirty minutes, after which they are removed and filled to within an inch of the top with cold water, the action of the ferment being stopped by this. One drop of iodine solution is added to each tube, starting with 5, and the tubes are shaken. Suppose that tubes 5 and 4 give a distinct blue colour, but tube 3 is colourless, the conclusion is that the amount of diastase in the urine added to tube 3 is just sufficient to digest 2 c.c. of the starch solution in half an hour. It is usual to express the result by dividing 2 (the amount of starch solution used) by the number of c.c. of urine in the tube which is just colourless to the iodine test—in the case just given the diastase coefficient would be $\frac{2}{0.3} = 6.6$; and if the kidneys are efficient the figure should not be

less than 6. The greater the kidney efficiency, the nearer to tube 5 will be the resultant first blue reaction when the iodine is added. If tube 1 gives the blue colour the inference will be that the renal efficiency is bad, for the diastase coefficient would then be only $\frac{2}{1.0} = 2$; whilst if 5 gives no blue reaction the diastase reaction is good, viz., $\frac{2}{0.1} = 20$.

The test by estimation of the urea in the blood: This can hardly be done in the consulting room, but needs the assistance of the special clinical laboratory. The specimen sent to the latter is a measured quantity of blood from the patient. It is obtained by puncturing

a vein with a suitable needle attached to a convenient syringe : the best veins are those in the antecubital fossa, rendered full by compression of the upper arm by means of a sphygmomanometer bag up to a pressure of about 90 mm. Hg or a little higher—at any rate a pressure well below the maximum systolic arterial pressure. The vein is punctured, and about 2 c.c. of blood are drawn up into the syringe : the amount of blood needs to be measured with accuracy, and it is then expelled into a bottle containing either 100 c.c. of absolute alcohol or about the same amount of trichloroacetic acid. The amount of alcohol or acid need not be known accurately. The alcohol or acid precipitates the serum albumin, serum globulin, and fibrinogen, but the urea and some minor constituents of the blood are kept in solution. At the laboratory the solution is filtered, the filtrate is evaporated to dryness, the residue dissolved in water, and the result estimated for urea by the sodium hypobromite method : if the original amount of blood used is known with accuracy, a simple calculation now gives the number of mgrm. of urea per 100 c.c. of blood. In health the figure is about 25 mgrm. per cent, and it should not exceed 40 mgrm. per cent ; any higher figure indicates pathological urea retention, and in severe cases the amount may be anything from 50 to 100 mgrm. per cent.

Herbert French.

ALBUMOSURIA may be discussed under two main headings, namely : (1) *Ordinary Albumosuria*, which is not uncommon but is of little clinical importance ; and (2) *Bence-Jones Albumosuria*, which is rare but is clinically important.

1. **Ordinary Albumosuria** is seldom recognized because the albumose generally occurs along with albumin, and is not detected until this has been removed by acidulating with

acetic acid, boiling thoroughly, and filtering. Albumose may be recognized in the filtrate by the fact that with Heller's nitric acid test it gives a white cloud which disappears on warming, to reappear on cooling ; and its presence may be confirmed by the violet-red colour it gives with the biuret test, which consists in adding excess of caustic soda to a drop of dilute copper sulphate solution, adding this mixture in drops to the urine, from which all albumin has been removed, and warming. Another test for albumose is Hofmeister's, which consists in acidulating the urine with acetic acid and then adding phosphotungstic acid ; albumoses give a milky cloud with the latter. The deutero-albumose that gives these tests occurs in the urine under a great variety of circumstances ; apparently the one essential factor is cell destruction within the body. It will suffice to mention some of the many diseases in which it has been found :—

a. '*Febrile*' *Albumosuria* : in severe infective fevers, such

Fig. 24. Skiagram showing multiple myelomata of the vertebrae, ribs, sacrum, and iliac bones. The condition was associated with Bence-Jones albumosuria. The diagnosis was verified by histological examination. (Kindly lent by S. Abeyn Smith, Esq., F.R.C.S. Ed.)

as typhoid, scarlet fever, small-pox, measles, acute rheumatism, lobar pneumonia.

b. '*Pyogenic*' *Albumosuria* : in empyema, phthisis with cavitation, bronchiectasis, appendicular, subdiaphragmatic or hepatic abscess, suppurating gall-bladder, pyosalpinx,

suppurative periostitis, arthritis, osteomyelitis, gangrene of the lung, gangrene of the leg, breaking-down cancer, acute peritonitis.

c. '*Hepato-genous*' *Albumosuria*: in cancer of the liver, cirrhosis, catarrhal jaundice, phosphorus poisoning, acute yellow atrophy, infective cholangitis, suppurative pylophlebitis.

d. '*Alimentary*' *Albumosuria*: in cases of gastric or duodenal ulcer, carcinoma of the colon or stomach, ulcerative colitis, tuberculous ulceration of the bowel, acute and chronic dysentery.

e. '*Hæmato-genous*' *Albumosuria*: in leukaemia, scurvy, purpuric conditions, and with internal hæmatomata, such as pelvic hæmatocele.

f. '*Albuminuric*' *Albumosuria*: many cases of acute nephritis, syphilitic, cardiac and other forms of albuminuria, are associated with albumosuria. There is some doubt, however, as to whether the reagents employed in the qualitative analysis do not themselves convert some of the albumin into albumose.

g. *Albumosuria due to unclassified causes*: such as pregnancy, especially if the foetus has died, though sometimes even without this.

The amount of albumose present in any of the above conditions is seldom large, and diagnostically it has little if any significance except when it occurs apart from albumin. Even then its main importance lies in the necessity of not mistaking it for albumin. This error

Fig. 25. — Skiagraph showing a myeloma of a rib; the split pin is pointing to the tumour. The diagnosis was verified by operation and histological examination. (By Dr. C. Thorstan Holland.)

would only arise with the nitric acid test, for albumose does not form a cloud on boiling with acetic acid. It is urged by some that albumosuria in appendicitis points to abscess rather than to simple inflammation: that in a pleuritic case it points to empyema rather than to serous effusion: that in a meningitic case it points to the suppurative or epidemic cerebrospinal forms rather than the tuberculous: and so on. But it is very doubtful if the symptom can carry so much weight as this. In a given case the presence of ordinary albumosuria points to a graver prognosis upon the whole than if no albumose were present, but it is not particularly helpful in differential diagnosis.

2. **Bence-Jones Albumosuria**, on the other hand, though rare, is clinically important. The nature of the protein present is still undecided: it certainly is not ordinary albumose. Its most striking characteristic appears when the urine is warmed after acidulation with acetic acid to prevent precipitation of phosphates: long before the urine boils a dense milky precipitate appears, suggesting at first sight either phosphates or coagulated albumin: it attracts attention at once from the fact that on further warming it begins to clear up again, and after boiling it almost or completely goes. It will be realized that the precipitate cannot be albumin or phosphates, for not only would neither of these clear up at boiling-point in this way, but also the acidulation of the urine has been sufficient to prevent phosphates

Fig. 26. — Skiagraph from a case of multiple secondary deposits of carcinoma in bone, from a case of primary carcinoma of the breast. The secondary deposits are indicated by the palled areas in the ilium, ischium, sacrum, and femur. There was Bence-Jones albumosuria. (By Dr. C. Thorstan Holland.)

from coming down, whilst the temperature at which the dense sticky precipitate appears (about 60° C.) is far lower than that at which albumin coagulates. If any albumin is present at the same time the clearing at boiling-point will be but partial; the albumin should then be removed by boiling and filtration, when nitric acid added to the cold filtrate will give a white ring which redissolves on warming, to reappear on cooling, like that of albumose. This Bence-Jones proteid, when present, generally occurs in much larger amounts than ordinary albumose ever does, so that it is seldom overlooked unless it is mistaken for albumin. It may amount to anything between 1 and 20 parts per thousand, or more. It may be present on some days and not on others. It indicates, almost with certainty, that there is some affection of the bone-marrow; it might be due, for instance, to secondary deposits of malignant disease in bones, or to leukemia; but in the great majority of cases it has occurred in connection with multiple myelomata—Kahler's disease or myelopathic albumosuria of Bradshaw. Unless there is other evidence to the contrary, abundance of Bence-Jones proteid in the urine indicates multiple tumours involving the bone-marrow, and if these are not discoverable by palpation they should be looked for by skiagraphic examination of the various bones, including the vertebrae and ribs (*Figs. 24–26*). A blood-count should also be made, however, because the condition is far from uncommon in splenomedullary leukemia, and it has also been noted in lymphatic leukemia when the latter has not been of an acute type. *Herbert French.*

ALKAPTONURIA. (See URINE, ABNORMAL COLORATION OF, p. 902.)

ALLOCHEIRIA literally means 'other-handness.' It sometimes happens that when a patient is touched upon the back of his *right* foot, and is then asked where he has been touched, he says, "Upon the back of my *left* foot." This reference of sensations to exactly corresponding parts of the limbs or body on the wrong side is known as allocheiria. Experiments have shown that complete allocheiria results from transverse hemisection of the spinal cord. Sensory impulses travel the more readily up their own side of the cord, but can also pass by the opposite side if necessary; when they are compelled to do so, the brain interprets them as coming from that side of the body which usually sends impulses up this particular side of the cord. When a patient exhibits allocheiria, therefore, it generally indicates that there is a lesion affecting one side of the spinal cord, or the upward extensions of the tracts which convey sensory impulses from the cord to the brain. It is necessarily a rare symptom. It might result from a stab or a bullet wound damaging the cord unilaterally; or from a gumma or neoplasm of the cord or its meninges; it may be functional; rarely it may result from the cord being compressed more on one side than on the other by spinal caries, new growth, callus, or a fracture-dislocation; and occasionally it may be noticed when there is a cord disease which, though usually bilateral, happens to have advanced more rapidly on one side than upon the other, as in exceptional cases of disseminated sclerosis, tabes dorsalis, or softening from syphilitic endarteritis thrombosis. Except in functional cases, allocheiria will seldom be the only, or even the chief, feature in the case; paresis, pain, or some other symptom additional to the allocheiria will afford assistance in the diagnosis. *Herbert French.*

AMBYLOPIA.—(See VISION, DEFECTS OF, p. 920.)

AMENORRHŒA. The age at which menstruation first appears is very variable within certain limits, being influenced largely by climatic and racial peculiarities: in this country about fourteen may be taken as the average. When the menstrual flow has not become established it is usual to speak of primary amenorrhœa, whilst premature cessation of the flow after it has once been regularly established is known as secondary amenorrhœa. From the table of the causes of amenorrhœa below, it will be seen that some of them must of necessity give rise to primary amenorrhœa, whilst others more commonly produce the secondary variety. In investigating a case, therefore, it is important to ascertain first whether the condition is primary or secondary, and next whether it is real or only apparent. The latter condition, known as *cryptomenorrhœa*, implies that

the menstrual flow takes place but is unable to escape externally because there is some closure of a part of the genital canal. The congenital form of cryptomenorrhœa is the only variety met with at all commonly, acquired closure of a part of the genital canal being exceedingly rare. Stenosis of the vagina is not uncommon as a result of injury and infection, but a small sinus is usually left which suffices for the escape of the menstrual fluid. We are led to suspect cryptomenorrhœa when the patient volunteers the statement that she has pelvic pain, headache, and possibly vomiting, of monthly occurrence, in fact the usual menstrual phenomena, unaccompanied by any visible flow. A physical examination should be made at once in such a case, including abdominal palpation, inspection of the vulva, and a recto-abdominal bimanual examination. The common form is that in which the lower end of the vagina is imperforate, the hymen usually being visible on the outer side of the occluding membrane. The complete examination in such a case will reveal a fluctuating swelling reaching from the vulva to the pelvic brim, above which the uterus can often be palpated and moved about. It is further of considerable importance to make out whether the uterus and Fallopian tubes are distended with menstrual products along with the distended vagina, for in the presence of hæmatosalpinges the treatment is considerably modified: abdominal section is required in such a case to avoid rupture of the tubes when the vagina collapses after incision of the occluding membrane. Distention of the vagina or *hæmatocolpos* is complete in this case, but may be partial where the lower part of the vagina is absent, and then is likely to be accompanied by distention of the uterus (*hæmatometra*) and *hæmatosalpinx*. Complete absence of the vagina can only be inferred from physical examination, when the distended organ appears to be only the uterus.

Although a secondary phenomenon, acquired cryptomenorrhœa produces the same symptoms and requires the same kind of investigation as the congenital cases. It must not be forgotten that acquired closure of the vagina following the vaginitis of specific fevers may occur in infancy, and will then, of course, produce primary amenorrhœa.

CAUSES OF APPARENT AMENORRHOEA.

Congenital:—

Imperforate vagina	Imperforate cervix	Hæmatometra
Imperforate hymen	Double uterus with retention	Hæmatosalpinx.
Absence of the vagina	Hæmatocolpos	

Acquired:—

<i>Closure of the vagina:</i>	<i>Closure of the cervix:</i>
Due to specific fevers	Due to injury
Due to injury	Following operations

CAUSES OF REAL AMENORRHOEA.

Physiological:—

Before puberty	<i>Circulatory system:</i>	Various forms of insanity
After the menopause	Chlorosis	Cold just before or during menstruation
During pregnancy	Anæmia	Suggestion—fear of pregnancy
During lactation	Leucocythæmia	
	Hodgkin's disease	

Pathological:—

<i>Generative system:</i>	<i>Wasting diseases:</i>	Anorexia nervosa
Absence of essential organs	Malignant growths	<i>Altered internal secretions:</i>
Infantile uterus	Tubercle	Myxœdema
Small adult type of uterus	Prolonged suppuration	Exophthalmic goitre
Deficient ovarian activity	Diabetes	Addison's disease
Destruction of both ovaries by double ovarian growths, pelvic inflammation	Late stages of nephritis	Acromegaly
	Late stage of some forms of heart disease	Obesity
	Late stage of cirrhosis of the liver	Change of habits
Superinvolution of the uterus	<i>Nervous system:</i>	<i>Toxic:</i>
	Imbecility	After specific fevers
	Cretinism	Chronic poisoning by lead, mercury, morphia, alcohol

NOTE. —Real amenorrhœa may be (1) Primary with delayed onset; (3) Primary and permanent; (3) Secondary.

In considering the diagnosis of the causes of real amenorrhœa, the primary and secondary forms afford us an important clue to the possible causation. Suppose, for

instance, that menstruation has once been established regularly, it is clear that there cannot be any serious congenital anomaly of the generative system : the uterus and ovaries must at least be present and functional. We then must make a systematic examination of the generative, circulatory, nervous, and ductless-gland systems, in order to learn by a process of exclusion which group of causes we have to deal with. If, however, the amenorrhœa is primary and real, that is, the patient has no menses, our examination must first be directed towards finding out whether the essential organs, namely uterus and ovaries, are present, and are normal in size and shape as far as a bimanual examination can ascertain. If necessary, an anæsthetic may be given for this purpose, for it is often a matter of considerable difficulty to decide the question. If the fact of absence of the essential organs can be established, we are clearly justified in considering the amenorrhœa to be permanent, and the patient or her friends should be told of this.

Apart from congenital anomalies, it is remarkable how few lesions of the generative organs there are which produce amenorrhœa ; only those diseases which destroy both ovaries completely or render the uterus functionless can cause amenorrhœa, and under this heading we find only double ovarian growths, the late stages of pelvic inflammation (salpingo-oöphoritis), and superinvolution of the uterus. A tumour destroying one ovary as a rule has no effect on menstruation at all, provided the other is present and functionally perfect. It is possible for one ovary only to be functional ; for instance, that on the same side as the undeveloped half of a unicornuate uterus may be quite atrophic and functionless. The presence of two tumours in the abdomen symmetrically arranged with regard to the uterus will sometimes permit of the diagnosis of double ovarian destruction, especially in the case of malignant growths, but quite commonly one tumour is much larger than the other, and the double nature of the lesion cannot be established until the abdomen is opened. Superinvolution of the uterus is not difficult to recognize when we remember that it always follows pregnancy, and the small size of the uterus can be made out readily by bimanual examination and the passage of the uterine sound. The organ sometimes measures only $1\frac{1}{2}$ inches by the sound. It must not be forgotten that even in these cases the primary lesion may be an ovarian atrophy, but very little is known on this point. The term 'deficient ovarian activity' is a time-honoured one, and must be taken to mean the absence of the internal secretion of the ovary. It is obvious that this condition cannot be diagnosed by any physical examination, and its presence can only be inferred when absolutely no other lesion of any system can be found to account for amenorrhœa, either primary or secondary.

It is impossible in the space at our disposal to draw up any detailed method by which the various diseases under the circulatory, nervous, etc., systems can be diagnosed : these are discussed under the headings of other symptoms that they produce. It is, however, not out of place to note here that amenorrhœa caused by general diseases, unconnected with the generative system, depends upon : (1) Alterations in the blood itself ; (2) Alterations in blood-pressure ; (3) Altered relation of the nerve impulses which form part of the stimulus for menstruation ; (4) Altered relations between the internal secretions of the ovary and the thyroid glands on the one hand, opposed to the suprarenal and pituitary glands on the other. Finally, with regard to pregnancy, which is the commonest of all causes of secondary amenorrhœa, it may be formulated as an axiom that an otherwise healthy woman who has had perfectly regular menstruation is probably pregnant if she has a period of absolute amenorrhœa. Nevertheless, the presence of pregnancy must never be assumed without a most careful consideration of the history, combined with a complete physical examination. The diagnosis of pregnancy must always be made upon a complex of symptoms rather than upon any one ; the combination of amenorrhœa, secretion to be squeezed from the breasts, morning sickness, vaginal discoloration, and an abdominal tumour, can only mean pregnancy in the vast majority of cases. The addition of fœtal movements and the fœtal heart-sounds makes the diagnosis absolute.

T. G. Stevens.

AMNESIA (Loss of Memory).—Memory is one of the higher functions of the brain, and presents wide variations in its degree of development in different individuals. The physiological range being so extensive, it is almost impossible to say whether an apparently poor memory is pathological or not, when the condition is of long standing and stationary.

Slight degrees of impairment of memory are of interest to the psychologist, but to the majority of medical men the loss must be considerable or of peculiar character before it is of diagnostic importance. In some forms of excitement there may be exaltation of memory (hypermnnesia): events are recalled and magnified in importance, which in normal states would never have reached the surface of conscious memory. In all forms of dementia, on the other hand, memory becomes impoverished (hypomnesia), and may eventually fail altogether (amnesia). Reference can be made to only a few states in which the condition of memory may be of service in diagnosis.

Dementia. In all forms of dementia—senile, general paralytic, toxic, etc.—memory is impaired, and it is the rule to find that recent events are lost before those belonging to distant years. Even when memory is obliterated almost completely, a few isolated events in the past may be recalled distinctly without their surroundings, and may take a prominent place in the patient's personality. These traits characterize senility, but are also to be found, when looked for, in other demented states.

Epilepsy. Amnesia is an important feature of the epileptic seizure: in the majority of epileptics no memory of the convulsion is preserved, although events immediately preceding it may be retained clearly, as well as those which follow the return of consciousness: in other cases the amnesia may cover a period preceding the attack (retrograde amnesia), while in others, actions are performed after the attacks, in an apparently conscious state, which the patient is quite unable to recall later on. To this phenomenon may be applied the term 'anterograde amnesia' in association with post-epileptic automatism. Epileptic amnesia is often important in connection with medico-legal questions and criminology. In addition to temporary lapses of memory, the majority of epileptics suffer from the progressive hypomnesia common to all forms of dementia. It is one of the first signs of their intellectual deterioration, and not the result of the administration of bromides to which it is generally attributed.

Trauma. Severe falls or blows on the head often cause complete amnesia: the latter may cover not only a period of unconsciousness, but also a period preceding or following it, or both. As in cases of epilepsy, the amnesia may be retrograde, anterograde, or anteroretrograde. The length of retrograde amnesia which persists after an injury to the head is a useful indication of the severity of the injury to the brain and of the amount of complete rest required in the treatment of such cases.

Korsakow's Syndrome. This condition, generally the result of alcoholism, is characterized by hypomnesia, disorientation, and pseudo-reminiscences. The patient loses memory for recent events, has no appreciation of time or place, talks freely and often plausibly about events which have never occurred, and yet may retain a very natural attitude of mind towards his surroundings. So natural may be his manner of talking and his behaviour, that the above-mentioned mental deficiencies may escape notice unless the medical man applies himself to their discovery.

Toxæmia. In many infective diseases, such as enteric fever, the return of health may reveal a state of amnesia covering a considerable part of the patient's illness, and this blank, the result of intoxication of the higher cerebral centres, may be permanent. While amnesia may be produced by any variety of general intoxication, the result of microbe or other poisons, such as alcohol, aluminium, manganese, it is particularly prevalent in conditions such as encephalitis lethargica in which the brain is the site of an infective inflammation.

Hysteria.—Amnesia is probably quite complete in connection with some forms of hysterical 'fits'. The patient in the interval between attacks has no recollection of the latter, although they are not associated with loss of consciousness. This fact underlies the theory which assumes a double consciousness: the person in one state of consciousness has no memory for events which occur in the other. The characteristic feature of hysterical amnesia, which distinguishes it from other varieties, is that the memory for lost events can be restored by hypnotic or other forms of suggestion.

E. Farquhar Buzzard.

ANÆMIA is a general and inexact term which may include one or more, or even all, of several different changes in the blood, but of which the main criterion clinically is diminution in the amount of hæmoglobin contained in a given volume, usually but not

invariably associated with a decrease in the number of red cells per c.mm. of blood. Changes in the leucocytes are not essentially related to anæmia, though their behaviour affords means of diagnosing some forms of anæmia from others. Various terms have been used to denote different ways in which the blood may depart from the normal: *oligocythæmia* or *hypocythæmia* both signify a diminution of the number of red cells below the normal 5,000,000 per c.mm. of blood in a man, 4,500,000 in a woman. *Oligarmia* means a diminished total amount of blood in the body; *hydræmia*, an increased percentage of water in the blood; *polyplasmia*, an increase in the volume of the plasma of the blood such as occurs in chlorosis; *oligochromæmia*, a diminution in the amount of hæmoglobin per c.mm. of blood.

For purposes of comparison of one case with another, one speaks of the red cells and of the hæmoglobin as being normally 100 per cent in health. An anæmia may be such that the hæmoglobin is greatly diminished without so great a diminution in the red corpuscles; it is also possible for the hæmoglobin and the red cells each to be diminished in equal proportions; and thirdly, it is possible for both the hæmoglobin and the red corpuscles to be diminished but for the hæmoglobin to be relatively less so than are the red cells. The red corpuscles contain relatively less hæmoglobin than they ought to in the first variety of anæmia, which is probably the commonest of all; in the second group, although there is anæmia, each red corpuscle contains its full quantity of hæmoglobin; whilst in the third group, although there is anæmia, each corpuscle contains more hæmoglobin than it normally should. As a means of expressing these facts shortly, one speaks

of the *colour index*: this is the ratio of the hæmoglobin to the red corpuscles. If the red corpuscles and hæmoglobin are each 100 per cent of normal, the colour index is $\frac{100}{100}$, or 1. If the hæmoglobin were diminished to 40 per cent of normal, whilst the red cells were only diminished to 80 per cent of normal, the colour index would be $\frac{40}{80}$, or 0.5—the *chlorotic type*, in which the index is less than 1. If the hæmoglobin and the red cells were both diminished to 50 per cent of normal, there would be anæmia with a normal colour index of $\frac{50}{50}$, or 1. If the hæmoglobin were diminished to 30 per cent of normal, whilst the red cells were diminished to 20 per cent of normal, the colour index would

Fig. 27.—A METHOD OF MAKING A BLOOD-FILM. A drop of blood is received at one end of a microscope slide: a second slide is laid transversely across the first, as shown; the blood being in the acute angle behind it, the transverse slide is carried steadily forward over the surface of the first, drawing the blood after it in an even film.

be $\frac{30}{20}$, or 1.5—that is to say, greater than 1, a condition which is spoken of as anæmia with a *high colour index*, such as seen with greatest constancy in pernicious anæmia.

Pallor may or may not indicate anæmia. Many persons look almost white and yet

blood is not in an abnormal condition. Pallor is normal in night-workers and in those who work underground. Even in some daylight workers the distribution of the cutaneous capillaries seems to be such that the superficial skin has little, if any, of the normal colour of blood, and yet the individuals are not anæmic in the sense of having any diminution of the hæmoglobin or the red cells. The error of mistaking mere pallor for anæmia is avoided by means of a blood-count, which in all cases should include estimation of the percentage of hæmoglobin, and of the total number of red cells, per c.mm.; and in most cases determination of the number of leucocytes per c.mm., a differential leucocyte count, and an examination of the characters of the red corpuscles in stained blood-films also (Fig. 27).

Corpuscles are best counted by means of the Thoma-Zeiss or Thoma-Leitz haemocytometer; hæmoglobin is measured most accurately by the Haldane-Gowers hæmoglobinometer; and blood-films are best fixed and stained simultaneously by means of Jenner's stain, or, when hæmatozoa are to be looked for, by Leishman's stain. Full directions as to the use of these instruments and stains are generally issued with them, or a handbook on laboratory methods may be referred to.

Having proved that the patient is suffering from real anæmia, that is to say from diminution in the percentage of hæmoglobin, and probably from a diminution in the red cells also, the next step in the diagnosis is to determine what is its nature. Attempts are

sometimes made to fit all cases of anæmia into one or other of two main groups, labelled *primary* and *secondary* respectively; but this is not really very helpful clinically. In many cases the nature of the anæmia is obvious at once—it may be secondary to post-partum hæmorrhage or other blood-loss, or the later stages of phthisis, syphilis, cancer, or malarial cachexia, and so on. Sometimes, however, even though anæmia is really due to a cause which in some patients is obvious, it is not obvious in the patient with whom one happens to be dealing, and then the diagnosis has to be arrived at by a process of exclusion. One need but mention as examples, perhaps, the difficulties that arise sometimes in diagnosing between fungating endocarditis, gastric carcinoma, and pernicious anæmia; or between anæmia due to blood-loss and blood-loss due to anæmia. In arriving at the diagnosis it is important first to exclude those conditions in which the blood picture is itself positive.

A division of all cases of anæmia into (A) *Anæmias with a positive blood picture*; and (B) *Anæmias with an indeterminate or negative blood picture*, is probably more helpful clinically than any other classification. The only anæmias in which the blood picture can be described as itself positive—that is to say in which the diagnosis is indicated directly by the results of blood examination—are (a) pernicious anæmia, (b) splenomedullary leukaemia, (c) lymphatic leukaemia, (d) mixed varieties of leukaemia, (e) parasitic anæmia associated with eosinophilia, and (f) parasitic anæmia associated with parasites in the blood.

Blood Changes common to all Severe Anæmias. In any severe anæmia there are certain blood changes which are almost always to be found, not pathognomonic of any one variety of anæmia, but, seeing that pernicious anæmia in its later stages is probably the profoundest of all the anæmias, better seen in it than in any other disease. These are:—

1. A very great diminution in the *number* of red corpuscles, down even to so low a figure as 600,000 per c.mm.

2. Great variation in the *shapes* of the red cells—*poikilocytosis*: poikilocytes (*Fig. 32*) always retain a smooth, curved outline, but instead of being flat circular discs, like normal corpuscles, they may be oval or pear- or hourglass-shaped, and so on. It is important not to mistake crenated corpuscles (*Fig. 31*), or red cells that have become polygonal by reason of mutual moulding when fixed in too close apposition with one another (*Fig. 30*), for poikilocytes.

3. Alterations in the *sizes* of the corpuscles—*anisocytosis*. In normal blood the red cells are almost all of the same diameter, about $7\ \mu$ (*Fig. 28*); in any severe anæmia they may vary considerably in size, many being much smaller than normal—*microcytes* (*Fig. 29*); some larger than normal—*macrocytes* or *megaloeytes* (*Fig. 29*).

4. The presence of *nucleated red corpuscles*. Normally none are present in the blood even in infancy; in any severe anæmia they may appear in varying numbers, and according to their sizes they are termed *microblasts*, *normoblasts*, *megaloblasts*, or *gigantoblasts* (*Fig. 33*).

the latter often containing more than one nucleus. It has sometimes been stated that the greater the number of nucleated corpuscles the less favourable the prognosis; but this is not necessarily the case, except in so far that it is unusual for nucleated forms to appear until a severe stage of the anæmia is reached.

None of the above changes, one must repeat, are diagnostic of any particular variety of severe anæmia, though they are perhaps most marked in the later stages of pernicious anæmia.

Normal Varieties of White Corpuscles. It often happens that variations in the relative proportions of the different leucocytes in the blood afford means of differential diagnosis. Before changes from the normal can be understood it is necessary to say a word or two about the normal varieties of white cells; these number anything from 5000 to 10,000 per c.mm., the total changing considerably at different times of the day. When films are made it is found that four easily distinguishable varieties are to be seen. These have received different names at the hands of different observers, but they are so distinct that names hardly matter, and they might be termed quite well types A, B, C, and D respectively. If, however, one has to choose between the different names that have been given to them, the following may perhaps be selected as the most frequently employed: (1) *Small and large lymphocytes*; (2) *Large hyaline corpuscles*; (3) *Polymorphonuclear cells*; (4) *Coarsely granular eosinophil corpuscles*.

1. The *small and large lymphocytes* (Fig. 35) stain blue with Jenner's stain, both as to nucleus and protoplasm. The nucleus is round, and the protoplasm is relatively small in amount and free from granules.

2. The *large hyaline corpuscles* (Fig. 37), stain blue, both as to nucleus and protoplasm. The nucleus is more or less kidney-shaped, and the protoplasm relatively large in amount and free from granules.

3. The *polymorphonuclear cells* (Fig. 38) stain blue as to the multilobed nucleus, red as to the relatively abundant protoplasm, which under the high power is seen to be speckled with very fine red granules.

4. The *coarsely granular eosinophil corpuscle* (Fig. 39) stain blue as to the multilobed nuclei, red as to the protoplasm, the amount of which is approximately the same as in the polymorphonuclear cells, but differs from the latter in that it is studded with very striking large eosinophil granules.

The only difficulty that arises in making a differential leucocyte count in normal blood is that, whereas the small lymphocytes usually become fixed in such a way as to cover relatively small areas, so that the cells seem to consist mainly of nucleus, at other times they spread out flatter over larger areas, and then the rounded nucleus seems to be surrounded by much protoplasm (Fig. 36). A small lymphocyte flattened out in this way may be called a large lymphocyte by those who wish to distinguish the latter from the small lymphocytes or small mononuclears, but they should in any case not be confounded with the large hyaline corpuscles, from which they are distinguished by their round nuclei—the nuclei of the large hyaline corpuscles being reniform: *transitional lymphocyte* is a nondescript label applied by some to cells which cannot be defined accurately as either small lymphocytes on the one hand, or large lymphocytes on the other. There is no deduction of particular clinical value to be obtained by distinguishing these cells from small lymphocytes; it is better that they should be grouped with the small lymphocytes for clinical purposes at any rate, only undoubtedly large hyaline cells with reniform nuclei being included in the group of large hyaline corpuscles.

The relative proportions of these cells differ according as the individual is a child or a grown-up person; for an adult one may say that, roughly speaking, out of 100 leucocytes,

About 25 will be small or large lymphocytes
.. 8 will be large hyaline corpuscles
.. 65 will be polymorphonuclear cells, and
.. 2 will be coarsely granular eosinophil corpuscles
—
100

In children the tendency is for the small lymphocytes to be relatively more numerous in health, and still more so in any illness—up to 40 per cent or even more—whilst the polymorphonuclear cells are correspondingly diminished.

Some observers prefer to represent the different varieties of white corpuscles not as stages but as total numbers per c.mm. of blood; but the general conclusions to be drawn are much the same whether the corpuscles are represented as percentages of totals or as relative totals per c.mm.

Abnormal Varieties of White Corpuscles. Whereas the above are the only kinds of white cells that need to be differentiated in healthy blood, in certain diseases two abnormal forms are met with:—

1. *Myelocytes*.—These are large corpuscles (Fig. 40), comparable in size to the polymorphonuclear cells, but differing from the latter in having either a perfectly round, an oval, or possibly a slightly kidney-shaped nucleus, rather than a multilobed one. There are all gradations of them, and at the two extremes it is difficult to differentiate some from large lymphocytes or large hyaline corpuscles and others from polymorphonuclear cells. They are to be distinguished from the latter by the roundness of the nucleus, and from large lymphocytes and large hyaline corpuscles by the granularity of the protoplasm. The granules in question are sometimes stained brightly with eosin—*eosinophil myelocytes* (Fig. 41), distinguishable at once from the ordinary eosinophil corpuscles by their nuclei being nearly spherical; more often, however, the granules stain blue, or some colour between blue and red—*basophil* or *neutrophil myelocytes*. No useful clinical

information can, so far as is at present known, be obtained by laying stress upon these differences in the staining reactions of different myelocytes, so that they are usually counted together simply as myelocytes. There is only one condition in which they are very numerous, and that is splenomedullary leukaemia; but they may occur in small numbers in various other affections, particularly in lymphadenoma, Hodgkin's disease, pernicious anæmia, splenic anæmia, cirrhosis of the liver, familial splenomegaly, acholuric jaundice, and aplastic anæmia.

2. *Basophil Corpuscles* (*Fig. 42*).—These are much smaller than myelocytes, their size being comparable to that of small lymphocytes; they differ from the latter in that the protoplasm, instead of being homogeneous, contains from 2 or 3 to perhaps 20 or more very large granules which stain deep blue with Jenner's stain. They are unmistakable. No definite clinical deductions can be drawn from their presence beyond the fact that, if there are more than 1 or 2 per 1000, the blood is abnormal. They may be present in many different varieties of anæmia, but they are not characteristic of any; they seldom amount to more than 2 or 3 per cent, and often to no more than 0·5 per cent, even in disease. They are said to be caused sometimes by the ingestion of certain chemicals, notably turpentine and its vapour, zinc oxide, and zinc sulphide, on which account they are met with occasionally in painters and in workers in zinc.

Punctate Basophilia.—There are certain conditions, particularly pernicious anæmia in its later stages, leukaemia, lead poisoning, and turpentine poisoning, in which the red cells, instead of staining uniformly pink with the eosin of Jenner's stain, present large numbers of small blue specks or granules in their protoplasm (*Fig. 34*), a condition known as *punctate basophilia*. In a case of doubt, when pernicious anæmia has been excluded by there being a low colour index, and when leukaemia is contra-indicated by the fact that there is a normal leucocyte count, the presence of extensive punctate basophilia is said sometimes to afford confirmative evidence of plumbism; but large numbers of cases of plumbism exhibit no punctate basophilia at all; and some authorities consider that the punctate basophilia of painters is due more to the effects of turpentine used in paint than to the effects of lead as such.

We may now pass on to consider the commoner varieties of anæmia, dealing first with anæmias with positive blood pictures.

A.—ANÆMIAS WITH POSITIVE BLOOD PICTURES.

1. **Pernicious Anæmia** is a disease of insidious onset in adults, the main symptoms being progressive loss of muscle-power and increasing pallor, with loss of weight, but with relatively less loss of body volume. Various other symptoms may be associated with these, or no others may be present. The diagnosis is seldom made until a relatively late stage of the malady has been reached, by which time there is a great diminution in the hæmoglobin, down perhaps to 30 per cent of normal or less, and a still greater diminution in the red cells, down perhaps to 25 per cent, 20 per cent, or even 10 per cent of normal; consequently the colour index is high, and this is the pathognomonic sign of the disease. There is no leucocytosis, but rather leucopenia (p. 454): the differential leucocyte count shows a relative increase in the small lymphocytes, a corresponding diminution in the polymorphonuclear cells, normal numbers of eosinophil corpuscles and large lymphocytes, occasional basophil corpuscles, and one or two myelocytes. Blood-films (*Fig. 43*) also show all the changes described above (p. 27) as common to any severe anæmia, but with particularly large relative numbers of megalocytes. When these blood changes are all present there can be no doubt about the diagnosis, and there is no need to enter here into all the other symptoms that may be presented by the patient. It is important to bear in mind, however, that there is one group of the cases in which mental symptoms predominate before the anæmia is pronounced; or the patient may first come under notice for symptoms and signs of gross changes in the spinal cord, such as those of disseminated sclerosis, lateral sclerosis, or combined sclerosis of the spinal tracts. The diagnosis of pernicious anæmia cannot be made without a blood-count, and it can usually be made absolutely with one; one word of warning is required, and that is that the colour index is not continuously high in every case of pernicious anæmia, so that perhaps several blood-counts may be necessary at intervals. It

should also be noted that the power of temporary recuperation is considerable, and when the patient's condition improves the blood may return partly or wholly to normal; during such remission the colour index, instead of remaining greater than 1, becomes 1 or less than 1.

There are certain cases of very severe anæmia which some would include under the heading of pernicious anæmia, although the colour index is persistently less than 1. It is more useful, however, from a clinical point of view to leave these cases unlabelled, or at

Fig. 13. Part of a blood film from a case of severe pernicious anæmia, showing poikilocytes, microcytes, megaloeytes, nucleated red cells, and punctate basophils.

any rate not to call them pernicious anæmia, which has so characteristic a blood picture. One variety has recently become separated from the rest under the title of *aplastic anæmia*, the chief characters of which are a profound, progressive, and ultimately fatal anæmia for which no cause can be found, which seems in many respects to simulate pernicious anæmia, but which is persistently associated with a low instead of a high colour index. It is, moreover, unaccompanied by reddening of the marrow in long bones like the femur, or by a positive Prussian-blue reaction in the liver—Perl's test with potassium ferrocyanide and hydrochloric acid—post mortem; this, when positive, is strongly confirmatory of

pernicious anæmia, for very few other conditions give it, and they are rare—sprue, for example, is one such, and bronzed diabetes another.

2. Splenomedullary Leukæmia.—In the earlier stages of this disease there is no anæmia at all, though later diminution both in the hæmoglobin and in the red cells may be profound. The essential point in the diagnosis is the occurrence of a very great increase of the total number of leucocytes, not at all uncommonly up to such a figure as 200,000, and sometimes up to 600,000 or even 1,000,000 per c.mm. There is only one other condition which can

Fig. 41. — Part of a blood-film from a case of splenomedullary leukæmia, showing five neutrophil myelocytes, one monophil myelocyte, three basophil cells, and one binucleated red cell, in addition to normal corpuscles. (Jenner's stain.)

produce so extreme an increase in the total number of leucocytes, and that is *lymphatic leukæmia*. The two are immediately distinguishable from one another by the differential leucocyte count, the characteristic point about which, in splenomedullary leukæmia, is the large number of myelocytes present. These may amount to 30, 40, or even 50 per cent, or more, of all the leucocytes present, with the consequence that there is a relative but not an absolute diminution in the other varieties of white cells. Occasional basophil cells are seen; but whatever may be the proportion of these or other leucocytes, the main point in the diagnosis is the large relative number of myelocytes in association with an

enormous increase in the total leucocyte count (*Fig. 44*). When anæmia ultimately ensues it is of the chlorotic type; that is, the hæmoglobin falls before, and to a greater extent than, the red cells. The disease generally lasts from one to three years before ending fatally, and in the later stages all the blood-changes characteristic of severe anæmia may be found. Clinically, the other main feature of the complaint is the enormous enlargement of the spleen, which here reaches dimensions bigger than in any other disease, the viscus often extending right across the middle line to the right iliac fossa or down into the pelvis. It is note-

Fig. 45.—Part of a blood film from a case of lymphatic leukaemia, showing a large increase in the small lymphocytes.

worthy that in patients treated with the X-rays or with radium, the spleen may become greatly reduced in size, and the blood picture may return nearly to normal, though it seldom if ever happens, even when the number of leucocytes per c.mm. has reached the normal, that there is an absence of myelocytes in the differential leucocyte count. Notwithstanding this apparent improvement in the blood and in the spleen, the length of time the patient survives does not seem to be increased.

3. **Lymphatic Leukæmia** (*Fig. 45*). There is no age at which any form of leukæmia may not occur; but upon the whole the splenomedullary form affects adults rather than

progresses, in a few instances, especially some time before the end, the colour index has been found to be greater than 1, as it is in pernicious anæmia. There is no likelihood of mistaking one condition for the other, on account of the changes in the white cells.

Some authorities describe two types of lymphatic leukaemia according as the lymphocytes seen in the films are of relatively large or small size; as has been explained above, however, there is always difficulty in deciding whether differences in apparent size of the lymphocytes constitute differences in kind, and there is no very great clinical purpose served in drawing the distinction here, unless perhaps that upon the whole the larger the lymphocytes present the greater the number of months the patient is likely to survive.

The chief difficulties that arise in the diagnosis occur in two ways: first, there are a few instances in which lymphatic leukaemia has run its course without any actual increase in the number of leucocytes per c.mm. of blood, the diagnosis being afforded only by the enormous relative increase in the small lymphocytes—*aleukæmic leukaemia*; and, secondly, children normally have a relatively high lymphocyte count, from which it happens that lymphatic leukaemia may sometimes be suspected in them when it is not really present. Suppose, for instance, a child suffers from an obscure illness associated with anæmia of the chlorotic type, with an increase in the leucocytes up to 25,000 per c.mm. and a relative increase of the small lymphocytes up to 55 per cent, would one be justified in diagnosing lymphatic leukaemia? One might be if there was general enlargement of the lymphatic glands and enlargement of the spleen; but otherwise both the leucocytosis and the relative increase in the lymphocytes might be due to some other complaint, and the only means of arriving at the diagnosis might be by awaiting developments. It is not safe to insist upon a diagnosis of lymphatic leukaemia unless there is either a very large increase in the total number of leucocytes, or a relative increase in the small lymphocytes up to 90 per cent or over, or both these changes at the same time.

Lymphatic leukaemia is not always a primary illness, however; there is a variety known as 'symptomatic leukaemia', which develops in a small proportion of cases of scarlet fever and perhaps of other acute infections. The blood picture at the beginning of the fever may be normal; later it may change, and the patient develops a blood state identical with that of acute lymphatic leukaemia; and he may die of this, though on the other hand it is not necessarily fatal: the blood picture may return to normal again after some weeks, and the patient may get well. It may be that these are but extreme examples of pyrexial lymphocytosis, and not really of leukaemia; but they naturally give rise to grave anxiety when the blood count makes it impossible for the time being to exclude the presence of actual leukaemia. On the other hand, there is no great enlargement of spleen or glands in these cases as a rule, and the condition might not be known to have existed at all if the practitioner in charge of them had not been assiduous in his hæmatological examinations.

4. Mixed Forms of Leukæmia.—Although the majority of cases of leukaemia belong either to the splenomedullary or to the lymphatic form, there are cases in which the symptoms and the blood changes partake of the character of both. Either the splenic or the lymphatic glandular enlargement, or both, may be marked; there may be no anæmia until the disease has passed its earlier stages, when the red cells and hæmoglobin pass through the chlorotic type of changes until they reach those severe alterations characteristic of all anæmias in their last stages; the white corpuscles show more or less increase in their total numbers, and the differential leucocyte count shows not only considerable numbers of myelocytes, such perhaps as 20 per cent or more, but also a great relative increase in the lymphocytes up to, it may be, 60 per cent or over. The occurrence of these cases of 'mixed' leukaemia would seem to indicate that there is really no absolute difference in kind, but rather only a difference in type, between the lymphatic and the splenomedullary forms already described.

5. Parasitic Anæmia associated with Eosinophilia.—Many varieties of the parasites that affect man produce hardly any blood changes at all—*Trichocephalus dispar*, *Oxyuris vermicularis*, *Ascaris lumbricoides*. Other parasites, however, produce very marked changes in the blood, and one may mention in particular *Tania solium*, *Tania mediocanellata*, *Bothriocephalus latus*, *Ankylostomum duodenale*, *Trichina spiralis*, *Bilharzia hæmatobia*, *Filaria sanguinis hominis*, and not a few cases of *hydatid* disease. The anæmia which results may be very profound, and the blood may exhibit all the changes described above as common to the severest anæmias. The colour index is usually low, but sometimes it

is greater than 1, simulating pernicious anæmia, especially in cases of ankylostomiasis; but whatever the total leucocytes, the differential count very commonly presents a considerable increase in the coarsely granular eosinophil corpuseles, and this EOSINOPHILIA (p. 271), in association with severe anæmia, suggests the presence of some toxic parasite. It does not indicate which parasite is present, however, this being determined by careful examination of the faeces, urine, and so forth (see PARASITES, INTESTINAL, p. 632).

6. Parasitic Anæmia associated with Parasites in the Blood.—The four best known diseases in which human beings have parasites in the blood are: malaria, filariasis, trypanosomiasis, and relapsing fever. In all these there may be much destruction of red cells with consequent anæmia of the chlorotic type. In most cases the history, particularly of residence in some tropical country where the disease in question is likely to occur, will suggest the diagnosis, and the examination of the blood, either fresh or in films, will be confirmative.

Relapsing fever used to be prevalent in Great Britain, and it still occurs in epidemic form in times of famine in association with uncleanness. It is commoner abroad. It is due to infection by the spirochæte of Obermeier (*Fig. 606*, p. 779) introduced into the

Fig. 48. Four hourly temperature chart in a case of severe relapsing fever.

body by the bites of bugs. It is a long spiral organism, 40μ long and 1μ broad, actively motile in fresh blood, but best seen in films stained with Leishman's stain. They first appear a day or two before the paroxysms of fever (*Fig. 48*), and may reach large numbers. In the intervals they are not to be found. The course of the disease usually suggests the diagnosis, outbursts of pyrexia associated with extreme prostration and severe illness, lasting about a week or rather less, alternating with intermissions of about the same length. There may be an indefinite number of relapses before the patient either dies or recovers.

Filariasis may be latent for a long time before it produces symptoms. Its best known effects are elephantiasis of the legs or genital organs, with or without chyluria. It occurs in many parts of the tropics, particularly in some of the Pacific Islands, such as Fiji; and in certain parts of China. The elephantiasis and the chyluria are due to mechanical obstruction to the pelvic lymphatics by the mature worms. The blood exhibits more or less anæmia of the chlorotic type, with a varying degree of eosinophilia, whilst at certain times of the day or night the peripheral blood also contains the long but narrow filarial embryos (*Fig. 603*, p. 779). There are probably different varieties of the organism, but they cannot be distinguished easily by the appearance of these embryos alone.

Without laying stress upon generic differences, it is important that in most cases they are to be found in the peripheral blood only at night (*Filaria bancrofti nocturna*); during the day they seem to retreat into the deep vessels; there are other cases, however, in which embryos, very similar in appearance, occur in the peripheral blood in the daytime and not at night (*Filaria diurna*); whilst in *Filaria perstans* they are present in the blood both night and day. Roughly speaking, one may say that each embryo when stretched out is $200\ \mu$ long and 4 to $5\ \mu$ wide, and they stain by Leishman's method. They may be found in the blood of patients who have returned to England after contracting the disease abroad.

Fig. 50. *Glossina morsitans*, $\times 10$. Compare with *Glossina palpalis*, Fig. 49. (Specimen kindly supplied by Lieut.-Col. MacArthur, R.A.M.C.)

Trypanosomiasis the cause of *sleeping sickness*. Trypanosomes of many different kinds are known to affect various animals, birds, and fish, but the only one which is important in man is the *Trypanosoma gambiense* (Fig. 604, p. 779). It is to be found in blood-films stained by Leishman's method months or years before it finds its way into the cerebrospinal fluid to produce sleeping sickness. It has a large and definite nucleus about its middle, surrounded by protoplasm which becomes prolonged into a relatively long undulating membrane terminating in a flagellum. It is an extra-corpuseular organism readily distinguishable when seen in its mature stage. It occurs particularly in people who have been resident in Uganda or other district in which *Glossina palpalis* (Fig. 49), the fly which spreads the disease, abounds. The diagnosis is much less easy when the blood contains only immature forms. It is sometimes easier to find the embryos in fluid obtained by puncturing the enlarged inguinal or other lymphatic glands often present in these patients.

One variety of severe anaemia occurring in Assam, associated with pyrexia and enlargement of the spleen, and formerly thought to be a variety of malaria, is due to a variety of trypanosomiasis in which immature forms of the *Leishmania donovani* (Leishman-Donovan bodies) have been found (Fig. 605, p. 779), not in the general blood-stream, but in the fluid obtained by splenic or hepatic puncture. The disease is termed *kala-azar* or *visceral leishmaniasis* (p. 780).

Malaria is not essentially associated with anaemia; but in patients who have had recurrent attacks, blood destruction by the parasites leads to considerable reduction both in the red cells and in the haemoglobin, the colour index generally being of the chlorotic type. The changes in the white corpuscles are described on p. 455. The diagnosis can

Fig. 51. Case of single tertian malaria, showing the attacks occurring every third day. (From the London School of Tropical Medicine.)

often be surmised when a patient who is, or has been, resident in a malarial district suffers from periodic rigors with pyrexia. Theoretically there are two main types of the disease, —the *tertian*, in which the paroxysms come on every alternate day with complete freedom every intermediate day (*Fig. 51*); and the *quartan*, in which there are two-day intervals, so that the paroxysms occur every fourth day (*Fig. 52*). Tertian fever may be caused by either the benign (*Plasmodium vivax*) or the malignant (*Laverania malarie*) tertian parasites. Quartan fever is due to *Plasmodium malaria*. The intervals between the fever waves vary in accordance with the length of time successive generations of these various species take to mature. What happens in a malarial district, however, is that after a patient has been infected by one set of mosquito bites with a tertian or quartan ague, he becomes infected

Fig. 52. Temperature chart from a case of quartan malarial fever, the attacks recurring every fourth day. (From the *London School of Tropical Medicine*.)

subsequently upon certain days by other mosquitoes with other tertian or quartan parasites, so that there is a mingling together of the effects of different broods of hamatozoa. For instance, if a patient had become infected by two tertian parasites, the one producing rigors upon Monday, Wednesday, Friday, and Sunday, and the other attacks upon Tuesday, Thursday, Saturday, and Monday, this patient would have a paroxysm every day, the type being then spoken of as *quotidian* (*Fig. 53*). If he were infected by two quartan parasites, the one producing attacks upon Monday, Thursday, and Sunday, and the other upon Tuesday, Friday, and Monday, the occurrence of the paroxysms becomes less regular, for the patient would have a rigor upon Monday, another on Tuesday, none on Wednesday, a rigor upon Thursday and Friday, but none on Saturday, and so on. Each infection by

Fig. 53. Temperature chart from a case of malaria to illustrate quotidian fever due to double tertian infection. (From the *London School of Tropical Medicine*.)

a fresh brood of malarial parasites complicates the clinical picture, until finally in those who have been long in malarial districts the attacks of pyrexia may be quite irregular or even almost continuous (*Figs. 54-56*). Each paroxysm has three characteristic stages, any one of which may last from half an hour to two or three hours, or more. The average duration of a paroxysm of benign tertian fever is eight hours. During the first or *cold stage*, the patient shivers with a severe rigor, feels cold, looks blue and pinched, but nevertheless has a rise of temperature to 102° F. or 103° F. The teeth chatter, and the patient wraps himself up to try and keep warm. This is followed by the *hot stage*, which begins with flushing of the face, severe headache, pains in the back, further rise of the temperature to 104° F. to 106° F., and a sensation of such heat that the patient throws off the clothes and calls for cooling drinks. This ends in the third or *sweating stage*, during which the skin, previously dry, breaks out into perspiration so severe that all the bedclothes may be wringing wet. The temperature now falls, and the patient, more or less exhausted, sleeps, and on waking feels comparatively well except for a sense of weakness; he may be able to do his ordinary work until the next paroxysm comes on. Only in a few cases do much severer symptoms supervene if proper treatment be adopted. In the absence of

treatment, however, malaria may lead to hyperpyrexia (107° F. -112° F.); to coma; or to a condition of algidity and collapse; any one of which may end in death. The malignant tertian parasite frequently gives rise to atypical fever paroxysms lasting more

Fig. 54. Temperature chart from a case of malarial fever illustrating severe tertian attacks alternating with mild tertian attacks due to double infection. (From the London School of Tropical Medicine.)

than eight hours; the fever curve it produces is lower than that of other forms of the disease, though dangerous symptoms such as coma, obstinate vomiting, choleraic diarrhœa, or collapse are far more common in infections with this parasite than with either of the others. The diagnosis may be confirmed to some extent by finding that the pyrexial outbursts diminish or cease altogether under the administration of quinine, but the only real proof of the nature of the complaint is the discovery in the blood of the malarial parasites (Figs. 57-60). It is important to note that the administration of quinine renders it difficult or impossible to find these in blood-films, and then the behaviour of the leucocytes (p. 455) may be very helpful. Albuminuria is common, and the urine generally contains urobilin during active malaria, ceasing to do so when the latter becomes latent; microscopically, golden brown pigment granules are often to be found in the

Fig. 55. Temperature chart from a case of malarial fever becoming complex from multiple malarial infection. (From the London School of Tropical Medicine.)

Fig. 56. Temperature chart to illustrate irregular pyrexia in chronic malaria. (From the London School of Tropical Medicine.)

centrifugized deposit; these and the urobilin together may point to the diagnosis when no parasites can be found in the blood. For a detailed account of all the stages and

Fig. 57.—*Plasmodium vivax*: causing benign tertian malaria. Three stages of development of the ring parasite (schizont) are shown; as the ring grows it expands the red corpuscle, and produces multiple small dots of dark pigment which distinguish it from the *Plasmodium malariae* of quartan fever, in whose case the pigment is in larger spots few in number. No crescents are formed. (stained by the Wright-Romanowsky method, and viewed under the $\frac{1}{2}$ -in. oil-immersion lens.)

Fig. 58.—*Plasmodium malariae*: causing benign quartan malaria. Two stages of development of the ring parasite (schizont) are shown; as the ring grows it does not expand the red corpuscle as does that of benign tertian (*Plasmodium vivax*), and the pigment particles are in the form of relatively large dots, few in number, instead of the multiple tiny dots of *Plasmodium vivax*. Crescents are not formed. (stained by the Wright-Romanowsky method, and viewed under the $\frac{1}{2}$ -in. oil-immersion lens.)

Fig. 59. *Plasmodium falciparum falciparum*, causing malignant tertian (or malignant subtertian, or active malarial) fever. Two stages of the ring parasite (schizont) and one crescent (gametocyte) are shown. The ring is larger than is that of the malignant quotidian parasite; the pigment granules are few and large, and the crescent is longer than is the red corpuscle infected by it. (stained by the Wright-Romanowsky method, and viewed under the $\frac{1}{2}$ -in. oil-immersion lens.)

Fig. 60. *Plasmodium falciparum quotidianum*, causing malignant quotidian malaria. Two stages of the ring parasite (schizont) and one crescent (gametocyte) are shown. Some authorities do not regard this parasite as distinct from *Plasmodium falciparum*; those who do so lay stress upon the pronounced smallness of the ring-parasite, and upon the small size of the crescent, which is not longer than the diameter of its original red corpuscle. (stained by the Wright-Romanowsky method, and viewed under the $\frac{1}{2}$ -in. oil-immersion lens.)

appearances of various malarial parasites, text-books of tropical medicine should be consulted; the following table gives a summary of the chief points of distinction:

THE DIFFERENTIAL CHARACTERS OF THE CHIEF TYPES OF MALARIAL PARASITES

	<i>Plasmodium vivax</i>	<i>Plasmodium malaria</i>	<i>Laverania malariv</i>
<i>Trophozoites</i>	Signet rings, often large growing forms very irregular, with vacuole; actively amœboid.	Signet rings, as in <i>P. vivax</i> ; growing forms less irregular, often band-like or angular; vacuole soon disappears; slightly amœboid.	Rings small, often with two nuclear granules, frequently attached to the edge of the cell; growing forms small, solid, rare in the peripheral circulation.
<i>Pigment</i>	Granules and rodlets, fairly fine; yellowish brown.	Granules and rodlets, coarser; darker brown.	One or two solid blocks or masses; almost black.
<i>Alteration in the red blood-corpuscle</i>	Hypertrophied and pale; stippling (Schüffner's dots)	Unenlarged or slightly contracted; in early stages slightly darkened; no stippling.	Size usually unaltered; in later stages paler, with coarse dots or irregular mottling (Maurer's dots).
<i>Adult schizont</i>	Larger than red blood-corpuscle.	Slightly smaller than red blood-corpuscle.	Distinctly smaller than red blood-corpuscle.
<i>Merozoites</i>	14 to 24 (average 18 to 20).	6 to 12 (average 8 or 9).	8 to 24, or more; very variable.
<i>Duration of schizogonous cycle</i>	48 hours.	72 hours.	24 to 48 hours (irregular).
<i>Gametocytes</i>	Round or slightly ovoid; much larger than a red blood-corpuscle.	Round or slightly ovoid; about the size of a red blood-corpuscle.	Crescentic or sausage-shaped.

All stages of development of *Plasmodium vivax* and of *Plasmodium malaria* may be seen in the peripheral blood, the more mature forms being described as rings which are intracorpuseular. *Laverania malariv* sporulates in the deeper organs, so that only young rings and crescents are to be found in films prepared from the peripheral blood, the characteristic crescents each with the ghost of a red corpuscle on one side of it not appearing until the disease is well established. One remarkable feature about malaria is that it remain latent for many years, and yet recur in those who have long since returned to Great Britain from the tropics. What has happened to the parasites in the interval is not known, but their reappearance is brought about by such conditions as general depression of health from overwork or worry, or as the result of some intercurrent malady.

B. -ANÆMIAS WITH AN INDETERMINATE OR NEGATIVE BLOOD PICTURE.

The diagnosis of the fact of anæmia is made by means of a blood-count, but in the great majority of cases the cause of the anæmia itself is not indicated by the blood condition. The differential diagnosis has to be made on other grounds. One may subdivide *Group B* into four sub-groups, namely: (1) Those cases in which the anæmia is slight and in itself not a very prominent symptom; e.g., in an indoor worker or a convalescent. (2) Those cases in which, though the anæmia may be severe, the routine examination of the patient discovers some more or less obvious and not absolutely uncommon cause for it; e.g., chronic tubal nephritis, gastric carcinoma, infective endocarditis, menorrhagia, hæmatemesis. (3) Those cases in which, though the anæmia may be severe, no obvious lesion can be discovered, but in which there is nothing about the case to suggest that the condition is a rare or unusual one; e.g., chlorosis. (4) Those cases in which the anæmia may be more or less severe, in which there may or may not be obvious lesions to account for it,

but in which the circumstances of the case suggest that the disease is unusual or rare ; e.g., chloroma.

1. Cases in which the Anæmia is slight and in itself not a very prominent symptom. - It is clear that before any anæmia that is not due to acute blood-loss from internal or external hæmorrhage reaches a severe stage, it must pass through a phase in which it may be regarded as slight or mild. This group therefore really includes all the other groups at some stage of their development, and the diagnostician will often label a case to start with comparatively mild or unimportant, when the course of events ultimately shows that this was wrong. For instance, a case of pernicious anæmia may exhibit what seem to be unimportant symptoms for months or years before the anæmia reaches so definite and severe a stage as to be diagnosed correctly. The group now under discussion is meant to include only such slight degrees of anæmia as are themselves not important in the matter of diagnosis : for instance, in people who live too much indoors, in those who are convalescent from some illness, in those who suffer from chronic indigestion, constipation, obesity, some forms of chronic intoxication by microbial products, due to such things as infective synovitis or arthritis, pyorrhœa alveolaris and oral sepsis (*Figs. 61-63*), uterine or ovarian disease, the earlier stages of phthisis, latent or deep-seated caseous glands or tuberculous affection of joints, vertebrae, or peritoneum in children, the milder cases of plumbism, and so on : in all these cases there may be a sufficient degree of anæmia to attract some attention, but the diagnosis will rest upon other symptoms and signs than those connected with the blood. Sometimes the general state of the patient convinces one that the anæmia is the result of chronic microbic toxæmia, and yet it may be very difficult to decide with certainty what the exact focus of infection is. The patient may have pyorrhœa and septic tooth-roots, and yet these may merely coincide with tertiary syphilis, the latter and not the former being the cause of the anæmia : or, again, there may be chronic constipation and some peculiarity in the bacterial flora of the bowel, yet the anæmia may not be due to that nebulous condition 'intestinal stasis and toxæmia', but to toxic absorption from a pyosalpinx or from septic tonsils. It requires much sanity of judgement to decide upon the exact bacterial cause in patients of this kind ; but the data needed include bacterial investigations of the nose, tonsils, mouth, stools, urine, vagina : a Wassermann test ; X-ray examination of the teeth for septic troubles at their roots ; and perhaps even a tuberculin inoculation test.

2. Cases in which, though the Anæmia may be severe, a routine examination of the patient discovers some more or less obvious and not absolutely uncommon cause of it.

Hæmorrhage. Some of the most striking cases of anæmia in this group are those in which there has been recurrent or severe loss of blood. When the latter has been lost by epistaxis, hæmoptysis, hæmatemesis, hæmaturia, menorrhagia, metrorrhagia, metrostaxis, purpura, or by the escape of blood per rectum, the nature of the anæmia will generally be obvious, and the differential diagnosis will depend upon the cause of the particular hæmorrhage in question (see *EPISTAXIS*, etc.). One should insist upon a complete blood-count in all these cases, however, in order to exclude pernicious anæmia,

Fig. 61. Skiagram showing an apical abscess at the root of the left lateral incisor, in contrast to the relatively normal apices of the canine and first and second premolars.

Fig. 62. Skiagram showing decided apical infection.

Fig. 63. Skiagram showing two premolars and a first molar, the latter crowned and showing apical infection of both roots, the anterior more than the posterior. This skiagram also illustrates rarefaction of the bone of the jaw and alveolar absorption, the upper border of the alveolar margins in the skiagram being not straight but serrated.

leukæmia, and the other conditions in which the blood picture is positive, lest the bleeding be due to the blood state and not the blood state to the bleeding. The possibility of melæna should also be borne in mind, for without examination of the feces the extreme pallor resulting from loss of blood from such a lesion as a duodenal ulcer may not be diagnosed correctly. *Hæmophilia* should not be forgotten: the way the patient bleeds excessively from slight scratches or cuts will generally point to the diagnosis, especially if there is a family history of a similar condition, males being affected more than females. The blood-picture in hæmophilia is entirely negative, the anæmia that results from the bleeding being of the chlorotic type. It is sometimes stated that the result of blood-loss is to produce an anæmia in which the red corpuscles and the hæmoglobin are equally reduced, so that the colour index remains more or less normal: this may be true of an acute bleeding such as venesection or post-partum hæmorrhage, but the effect of recurrent blood-loss is to produce the chlorotic type of anæmia, in which the red corpuscles are less diminished than is the hæmoglobin.

Cachexia.—A similar blood picture, namely an anæmia of the chlorotic type more or less severe, but without anything which may be called pathognomonic, either as to the red cells or the leucocytes, is to be found in almost all forms of cachexia, whether due to syphilis, tuberculous or malignant disease, malaria, beri-beri and other tropical illnesses, œsophageal stenosis, or starvation. A careful physical examination of the patient and inquiry into his symptoms may point to the correct diagnosis; but it is to be borne in mind how difficult it sometimes is to detect phthisis, or some cases of carcinoma or sarcoma, even when far advanced. Sputum analysis should not be omitted: rectal examination should not be forgotten: the X-rays may serve to detect lesions within the thorax, and Wassermann's serum reaction should be employed even when syphilis seems unlikely. It is remarkable how little anæmia may result from some varieties of cancer, particularly carcinoma of the breast: whilst other varieties, especially carcinoma of the stomach, produce progressive anæmia comparatively early. Absence of free hydrochloric acid from the gastric juice at the proper interval after a test meal may afford evidence of carcinoma ventriculi, but hydrochloric acid may be deficient or entirely absent in many other conditions also; it is absent in almost all cases of advanced carcinoma, whether of the stomach or not; and in many chronic maladies associated with ill-health all the secretions of the body suffer, and amongst them the hydrochloric acid of the gastric juice. Nevertheless, when the diagnosis has been narrowed down to there being some lesion of the stomach, the discovery that free gastric hydrochloric acid is very deficient or absent affords evidence that the lesion is a carcinoma, especially if there is also occult blood in the stools at a time when the patient has had no food containing hæmoglobin or chlorophyll during the preceding three days.

Parasitic affections sometimes escape recognition, even when they have led to sufficient anæmia to attract attention (see PARASITES, INTESTINAL, p. 632). The two varieties most likely to be associated with anæmia are *Ankylostomum duodenale* and *Bothriocephalus latius*. *Leishmania hæmatobia* may also lead to severe anæmia, but generally does so on account of the HÆMATURIA (p. 347) that it produces. EOSINOPHILIA (p. 271) may suggest a parasitic infection.

Drugs.—Certain drugs may produce anæmia of the simple chlorotic type if their administration is continued over a long period; particularly *mercury*, *arsenic*, *lead*, and *salicylates*. Acute mercurialism is commonly associated with stomatitis and salivation, but in chronic cases, in addition to anæmia, there is apt to be a motor type of peripheral neuritis affecting the limbs and associated with a remarkable tremor (p. 882), particularly of the hands. The diagnosis is generally arrived at from the fact that the patient has been receiving mercury medicinally, or is employed in some work in which mercury is used, for instance, the making of thermometers or mirrors, or the curing of rabbit skins for the manufacture of furs or top-hats. *Arsenical poisoning* seldom gives rise to anæmia as its sole symptom; but it is noteworthy that although liquor arsenicalis is an admirable remedy for the relief of pernicious anæmia, arsenic itself is also a cause of anæmia amongst those who work in it. As a rule, in addition to anæmia there is marked pigmentation of the skin (*Fig. 505*, p. 643), and Addison's disease may be simulated. In the latter, however, the pigmentation occurs on the mucous membranes, particularly of the lips and cheeks, as well as upon the skin, and this—though in very exceptional cases a similar pigmentation within the mouth has

been observed in pernicious anæmia (*Fig. 64*), and perhaps after taking arsenic for long periods—is always very suggestive of Addison's disease, and the diagnosis may be confirmed by finding a slight degree of eosinophilia, a remarkably low blood-pressure, down even to 80 mm. Hg or less, attacks of vomiting, syncope, and pronounced asthenia. If there is active tuberculosis of the suprarenal capsules, Calmette's or von Pirquet's reactions with tuberculin may be positive, but these two tests are now less relied on than formerly. In arsenical cases there may also be evidence of peripheral neuritis and of hyperkeratosis of the soles and palms. Analysis of the hair will discover an abnormally high percentage of arsenic.

The chlorotic type of anæmia in *lead poisoning* may be extreme, but the diagnosis will depend upon other symptoms, of which any or all of the following may occur: a blue line upon the gums; constipation; nausea; vomiting; epigastric pains; abdominal colic; a tendency to repeated abortion in women; peripheral neuritis, particularly of the wrist-drop type; various cerebral symptoms of any degree, from mere headache or insomnia to epileptic convulsions or acute mania, or other serious mental signs summarized by the term *saturnine encephalopathy*; impairment of sight; optic neuritis; ophthalmoplegia, chiefly affecting the sixth cranial nerve; a tendency to gout, albuminuria, and granular kidney, and the secondary effects of the latter. The absence of a blue line on the gums does not exclude lead poisoning in those whose teeth are clean; nor does its presence prove lead poisoning, for most workers in lead exhibit a blue line whether they have other symptoms or not; and a less definite blueness of the gum-margins is sometimes due to bismuth. In cases of doubt, it may be necessary to collect an abundance of urine, evaporate it, and apply the ordinary tests for inorganic lead; or the stools may be incinerated and tested for lead, which is eliminated by the bowels as well as in the urine. The occupation of the patient will often suggest the diagnosis.

Salicylates are said to produce anæmia if their administration is continued for a long period; but it is possible that the anæmia may be due to the condition for which the salicylates are given, especially *acute rheumatism*. The diagnosis is generally obvious.

In addition to the anæmia that may result from acute rheumatism itself, there is apt to be pronounced anæmia in some forms of valvular heart disease, particularly *affections of the aortic valves*, whether rheumatic or syphilitic. Mitral disease, particularly mitral stenosis, is more likely to cause polycythæmia (p. 650), unless there is *fungating* or *infective endocarditis*. The occurrence of a progressive anæmia in chronic heart cases always arouses suspicion of the latter; most cases of fungating endocarditis present symptoms of failing compensation which are often very difficult to distinguish from those due to the mechanical effects of chronic valvular disease, so that it is often difficult to distinguish a heart case without fungating endocarditis from one in which fungating endocarditis has supervened.

Fig. 64. Pigmentation of the mucous membrane of the lips, cheek, and palate, in a case of pernicious anæmia in which no arsenic had yet been given. Addison's disease was simulated, but the diagnosis of pernicious anæmia was confirmed by autopsy.

In addition to anæmia the following points would be in favour of the latter : sudden and radical changes in the character of the heart bruits, for instance from musical to blowing, and vice versa ; enlargement of the spleen ; the occurrence of hæmorrhages, particularly subcutaneous or retinal ; optic neuritis ; pyrexia (*Fig. 65*), whatever its type, provided it cannot be explained by any intercurrent affection such as tonsillitis or pleurisy—though the absence of pyrexia does not exclude the disease ; rigors, though these are often absent ; and symptoms of infarction or embolism in the spleen, kidney, intestine, retinal or peripheral vessels, or brain, resulting in convulsions or paralysis ; cessation of pulse in one or other of the accessible arteries such as the radial, posterior tibial, or dorsalis pedis ; acute gangrene of some part whose circulation has thus been cut off suddenly—a toe, or the tip of the nose, for example ; the development of a spontaneous

Fig. 65.—Temperature chart, morning and evening, for twenty-three consecutive weeks in a case of infective endocarditis, to show the illusory apyrexial periods that are apt to occur and make one think that the diagnosis must be wrong, raising false hopes. The apyrexial intervals are quite different from the terminal hypothermia illustrated in *Fig. 562*, p. 704. This patient seemed to be almost holding his own, when he died suddenly from cerebral embolism.

peripheral aneurysm ; sudden hæmaturia ; sudden acute pain over the spleen, associated perhaps with a peritonitic rub. It is noteworthy that there is but little leucocytosis in infective endocarditis. Cultivations from the blood obtained by aseptic venesection may serve to clinch the diagnosis, and also to indicate what serum or vaccine treatment should be employed ; though it is remarkable how often blood cultures are negative in these cases, even when the blood is obtained during a period of high pyrexia ; it is seldom that a pathogenic growth results, unless the patient's temperature is at least 102° F. at the time the blood specimen is taken, and fully 5 c.c. of blood should be used for each culture.

It is in some cases easy, but in others relatively difficult, to be sure of the diagnosis of *subacute nephritis*. Anæmia is a prominent symptom in the chronic nephritis of young people, though the reverse is generally the case in the red granular kidney of later life ; for

the differential diagnosis, see ALBUMINURIA (p. 11). The old aphorism of "the large white person with the large white kidney" may sometimes suggest the malady.

Many subacute or chronic maladies associated with continued absorption of microbial toxins have anæmia as a prominent symptom. One may mention, for instance, *chronic colitis*, whether muco-membranous, 'simple' ulcerative, or tropical dysenteric (see DIARRHŒA, p. 214); deep-seated *suppuration* acts in the same way, and one is familiar with the pallor of patients suffering from empyema; the development of this anæmia after the crisis of lobar pneumonia, or in connection with bronchopneumonia in children, not infrequently suggests that an empyema has developed; the diagnosis may be confirmed by the physical signs, but it will be clinched by finding pus when the chest is needled. Leucocytosis or a relative increase in the polymorphonuclear cells does not help in determining the presence of empyema so much as in other cases of suppuration, because empyema is nearly always secondary to lobar or lobular pneumonia, and in each of these there is also a polymorphonuclear leucocytosis. Other examples of chronic sepsis which may produce severe anæmia are: chronic appendicular abscess; pyosalpinx; hepatic abscess; the breaking down of ovarian or uterine tumours; chronic endometritis; pyorrhæa alveolaris; infection of sinuses connected with bones or joints, particularly unclean tuberculous hip- or knee-joints; psoas abscess; suppurative periostitis or osteomyelitis, with necrosis of bone; secondary coccal infections in phthisis with cavitation, or in bronchiectasis; chronic tonsillitis with purulent secretion expressible from the lower pole of a tonsil which may not be very large and which does not seem diseased unless it is investigated with detailed care; chronic post-nasal catarrh; root-sepsis of teeth, even if there is no obvious pyorrhæa diagnosed by X-ray examination; chronic otitis media, or infection of the ethmoid, frontal, or sphenoid sinuses, or antral disease; chronic bacilluria; intestinal sepsis, diagnosable by skilled bacterial investigation of the stools. Chronic sepsis may produce *lardaceous disease*, which itself is also a cause of profound anæmia simulating that of pernicious anæmia, with a peculiar pale-yellowish or transparent appearance of the skin, though its diagnosis is exceedingly difficult in any but advanced cases. It is guessed at, as a rule, on account of there being a chronic purulent discharge from lung, joint, or limb, or else severe tertiary syphilis, together perhaps with enlargement of the liver and spleen, albuminuria, and a tendency to diarrhœa. Similar anæmia may be produced by *sprue* in its chronic stages; the diagnosis generally depends upon the development of the illness in some part of India, with sore mouth and tongue and frothing diarrhœa as prominent symptoms at the start.

Rheumatoid arthritis is an indefinite group of joint diseases which differ essentially from osteo-arthritis (p. 430), in that with the former there are more or less severe constitutional symptoms, including slight pyrexia, loss of appetite and weight, pigmentation of the skin, and anæmia. The nearest lymphatic glands, e.g., the epitrochlear when the hands are affected, are often enlarged and tender. The diagnosis seldom depends upon the anæmia, however. Probably there are many varieties of rheumatoid arthritis which should be classified upon a bacteriological basis into those due to gonococci, streptococci, staphylococci, pneumococci, Friedländer's pneumobacilli, *Bacillus coli communis*, *Bacillus dysenteriae*, *Spirocharta pallida*, and so on. There are two types that are particularly prone to anæmia, and these are, first, the form in which there is marked spindle-shaped enlargement of all the first interphalangeal joints in adults, whatever other joints may be affected at the same time (p. 426); and secondly, a general destructive affection of the joints in children, associated with emaciation, anæmia, and enlargement of the spleen and of the lymphatic glands, and known as *Still's disease* (Fig. 381, p. 472). (See JOINTS, AFFECTIONS OF, p. 423.)

Cirrhosis of the liver sooner or later

leads to anæmia of the chlorotic type, although in the earlier stages the alcoholic patient may have a rubicund complexion; by the time the anæmia is pronounced there will almost certainly have been other symptoms of the complaint, particularly HÆMATEMESIS (p. 336), JAUNDICE (p. 405)

Fig. 66. Temperature chart (morning and evening) from a case of cirrhosis of the liver, showing the tendency to pyrexia.

or ASCITES (p. 59). Patients with cirrhosis of the liver often have some evening pyrexia (Fig. 66), and they tend to undue pigmentation of the skin. The facies, with its combination of sallow pallor, diffuse but not perfectly pale-brown pigmentation, and fine telangiectases, is sometimes almost pathognomonic.

Hyperlactation is a prominent cause of anæmia and general ill-health, especially in women in towns. The cause for prolongation of the period of lactation is often an idea that pregnancy will not recur whilst the last infant is being suckled. The diagnosis is generally obvious if its possibility is borne in mind.

Gastric ulcer, or rather the symptoms which are often stated to be those of gastric ulcer, is frequently associated with anæmia: the latter in a few cases is the result of direct loss of blood by HÆMATEMESIS (p. 336), or, in the case of duodenal ulcer, MELÆNA (p. 481). A duodenal ulcer may sometimes simulate gastric ulcer, but more often it produces symptoms which are apt to be mistaken for gall-stones, the pain, if it is not epigastric, or in the middle line half-way between the epigastric angle and the navel, being referred to a spot about an inch below the tip of the ninth right rib. As a rule the pain in cases of duodenal ulcer bears a definite relationship to food, being greatest when the patient is beginning to be hungry, and relieved by the taking of food. Gastric ulcer, on the other hand, is much more difficult to diagnose, for even when the patients have suffered from epigastric pain coming on immediately after food, from vomiting which relieves the pain, and from one or more attacks of hæmatemesis, it is possible for the latter to be due to generalized oozing from the gastric mucosa—'gastrostaxis'—rather than a definite measurable ulcer. When there has been no hæmatemesis the diagnosis is still more difficult, though it is noteworthy that in nearly half the cases in which the presence of an ulcer has been proved by operation there has been no history of hæmatemesis. It was formerly stated that gastric ulcers are common in the female sex between the ages of fifteen and thirty, especially in the unmarried and the anæmic; notably amongst the servant class. Operative demonstrations of gastric ulcers, however, seem to show that they are really commoner in later life, and affect men as often as women, so that there is a very decided possibility that the gastric symptoms of anæmic women are not in fact due to ulcer. One meets with patients who have pain the moment they take food, in whom vomiting after meals is persistent, in whom the diagnosis of gastric ulcer would certainly have been made in former years, but in whom that diagnosis is made now only with considerable caution. It has become increasingly recognized that the vomiting and the gastric signs are often due to the anæmia itself, and result from anæmic dilatation of the heart. In diagnosing between this condition and that of true gastric ulcer, one plan is to put the patient to bed, and, when she has been recumbent for twenty-four or thirty-six hours, to see what is the effect of giving her full diet. Full diet will be borne quite well in cases of severe anæmia associated with gastric symptoms without ulcer so long as the patient remains in bed: but if she gets up and returns to work before the anæmia is cured, the gastric symptoms come on again directly. The vomiting and the epigastric pain seem to be related not so much to food as to work in these cases. When there is an ulcer, however, an attempt to adopt full meat and vegetable diet on the second day of resting in bed nearly always fails if there have been severe symptoms up to that time. Another condition, often associated with anæmia, and liable to be mistaken for gastric ulceration owing to concomitant epigastric pain after food, inability to eat ordinary diet, and liability to vomit with resultant relief, is gastropptosis or general visceroptosis—Glénard's 'disease'. It is commoner in women, but occurs in men too: it is relieved by an adequate abdominal support, but the diagnosis depends mainly on the results of serial X-ray examination after a bismuth or barium meal (see PAIN IN THE EPIGASTRIUM, p. 536).

3. Conditions in which, though the Anæmia may be severe, no obvious lesion can be discovered, whilst at the same time there is nothing to suggest that the case is a rare or an unusual one.

Chlorosis is almost the only malady which comes under this heading, if one includes the milder anæmias of girls and young women as well as the severe cases of yellow-green sickness to which the term should, strictly speaking, be limited. The cases of anæmic vomiting just discussed might also come under the same heading. Chlorosis and simple chlorotic anæmia, without obvious organic lesions, are affections of the female sex—absent before puberty and common immediately after, seldom lasting after thirty years of age, and generally not

so long : cured as a rule by marriage ; never fatal even when severe ; an affection of all classes, but mostly of indoor workers such as servant girls, and not often affecting those who are employed in outdoor pursuits. The diagnosis is generally easy. The patients are comparatively well covered though they often eat very little. Emaciation is rare in chlorosis, and this is probably due to the fact that the blood is less deficient in quantity than diluted by excess of water. The leucocytes are normal both in total number and in differential count. The red corpuscles are often much less diminished than might be expected from the appearance of the patient, the chief feature of the complaint being the great reduction in the hæmoglobin, so that the colour index may fall to 0·5, 0·4, or even less. As the condition improves, the red cells return to normal fairly quickly, and the hæmoglobin rises steadily but less rapidly. The way in which the patients react to treatment by rest in bed, by the giving of iron, by keeping the bowels open, and by living in a sunny atmosphere, is remarkable, and helps to clinch the diagnosis in any case of doubt. It has been mentioned above that there are many blood changes which are common to severe anæmias : it should be noted that even when the hæmoglobin has fallen to 30 per cent of normal in a severe case of chlorosis, the changes in the blood-cells enumerated on p. 27 seldom appear. Chlorosis, more often than any other form of anæmia, leads to hæmic cardiac bruits, particularly a blowing systolic bruit in the pulmonary area and a *bruit de diable* in the neck. The patients are often constipated, are apt to suffer from indigestion, pain after food, and vomiting, from menstrual irregularity, particularly amenorrhæa, which may last for months, and a tendency to œdema of the feet. The viscera are generally normal. Chlorosis, unlike many other forms of severe anæmia, seldom produces albuminuria. The condition in its full degree is much rarer than it used to be, perhaps because of the more open-air life that girls and young women have tended to live in latter years.

1. Cases in which the Anæmia may be more or less severe, in which there may or may not be obvious lesions to account for it, but in which the circumstances of the case suggest that the disease is unusual or rare.

Hodgkin's disease is often spoken of as though it were an affection in which the blood-count indicates the diagnosis. This is not the case, however, the blood changes being merely negative, though a blood-count is essential in order to exclude leukaemia by finding that there is no leucocytosis. At first there is no anæmia ; later there is progressive anæmia of the chlorotic type, with finally all the changes in the red cells common to the severe anæmias (p. 27). There is no leucocytosis, or none of moment. The differential leucocyte count may be normal ; more often, however, there is some relative increase in the lymphocytes with proportionate relative diminution in the polymorphonuclear cells, and when a large number of white corpuscles are examined occasional myelocytes and one or two basophil corpuscles will be detected. The diagnosis is made from the enlargement of the LYMPHATIC GLANDS (p. 471) and of the SPLEEN (p. 774).

Splenic anæmia is a malady in which there is considerable enlargement of the spleen, progressive anæmia of the simple chlorotic type, and no other very obvious evidence as to what is wrong with the patient. It is probable that more than one condition is at present labelled splenic anæmia ; a considerable number of the cases turn out ultimately to be cirrhosis of the liver (p. 780), in which enlargement of the spleen happens to have been the first symptom to attract attention, very likely years before the other effects of cirrhosis manifested themselves. When splenic anæmia is the original diagnosis in a case which ends ultimately as cirrhosis of the liver, the condition is often spoken of as *Banti's disease*.

Aplastic anæmia has been mentioned above (p. 31). There are a considerable number of other obscure types of severe anæmia to which up to the present no definite labels can be attached. Some of these simulate pernicious anæmia, but all differ from the latter in having a colour index persistently less than 1. One can only refer to them as severe and even fatal un-named anæmias.

Pseudo-leukæmia infantum is a condition in which enormous enlargement of the spleen takes place in a young child or infant (*Fig. 67*), associated as a rule with more or less ascites and enlargement of the abdomen. So great is the splenic enlargement sometimes that the condition at first suggests leukaemia ; but when a blood-count is made, although the red cells may be very much diminished and exhibit all the changes characteristic of severe

anæmia, there is no extreme leucocytosis, so that the condition cannot be classified as a leukæmia, and hence is termed 'pseudo-leukæmia infantum': it has also been called '*von Jaksch's disease*'.

Fig. 67. - Pseudo-leukæmia infantum (von Jaksch's disease). The black line demarcates the spleen.

It generally begins at an age of less than two years, or at any rate in early childhood, and it may affect more than one child in the same family. The liver is enlarged, but less so than the spleen. There may be severe hæmorrhage from the mucous membranes, and there is often periodic pyrexia. The disease may be mistaken for rickets or for congenital syphilis: indeed some authorities think that it is often due to one or other or both of these causes, though others regard the rachitic and the congenital syphilitic cases as essentially distinct from von Jaksch's disease. Whichever view is correct, the prognosis is fair if treatment by splenectomy is resorted to, even when the anæmia has reached a severe degree, many cases being restored to perfect health after the operation.

Acholaric jaundice (p. 415), with or without splenomegaly, and with or without congenital or familial incidence, is often associated with pronounced anæmia, but the icteric tint attracts chief notice.

Myxædema is a condition which may be mistaken for simple anæmia, and consequently it is apt to be overlooked, particularly at that stage which merits the term '*hypothyroidism*' rather than myxædema. It is an affection of women rather than of men; it comes on very slowly, and sometimes it can be diagnosed only by watching the beneficial effects of thyroid treatment. There is generally excess of gelatinous subcutaneous

tissue, which gives the patient a puffy or œdematous appearance, especially in the face (Fig. 68), hands (Fig. 70), and lower limbs, so that not a few cases are mistaken for nephritis. The urine is copious and of low specific gravity, but usually does not contain albumin: though in some cases there is sufficient albuminuria to make the case still more like one of Bright's disease. The apparent œdema does not pit on pressure, or pits far less easily than it would if it were ordinary œdema: the skin becomes thickened, and the hair decreases in quantity and becomes brittle. Physical movements are lethargic, and the intellect is dull, so that there is slowness of action both

body and of mind, symptoms that disappear in a remarkable way under thyroid treatment. A singer may lose voice-power from swelling of the parts about the larynx. In some cases the mental symptoms predominate to such a degree that some form of delusional insanity or dementia may be diagnosed, or even a cerebral tumour. The chlorotic type of anæmia which accompanies myxædema may be masked by a local flush over the malar bones, not unlike that of mitral stenosis (Fig. 78, p. 69)

Fig. 68. Myxædema: the characteristic faces, illustrating the broadening of the features and the malar flush. Compare Fig. 69.

Fig. 69. The same patient as Fig. 68, previous to the development of myxædema.

Scurvy is a rare disease which may lead to the most profound anæmia, though it seldom does so without also producing extensive hæmorrhage into the skin, beneath the periosteum of the tibiae or other bones, from mucous membranes, and especially from the spongy and fetid gums. It is not common nowadays, except in a mild form in children (*scurvy rickets* or *Barlow's disease*—in which tenderness of the bones associated with anæmia,

often mistaken for rickets, is the main symptom. The tenderness in question is due to local subperiosteal hæmorrhage, and the way in which the complaint rapidly gets better under suitable treatment with fresh vegetable diet helps in clinching the diagnosis. The severer forms of scurvy are due to prolonged deprivation of fresh food, such as is rare in modern practice, though it used to be common on board ships.

Chloroma is a very rare affection, related to lymphatic leukaemia on the one hand and to lymphosarcoma on the other. It is associated with the formation of multiple tumours, especially in connection with bones, and a progressive and severe anaemia of indeterminate type. The condition is fatal, and the diagnosis is at once suggested at autopsy by the green colour of the neoplastic deposits.

Certain other anæmic states, more or less related to the anæmias of the hæmolytic group in that there is a decided tendency to familial or congenital incidence, are of such rarity that they merit little more than mention; and yet when they occur their peculiarities attract considerable notice; amongst these, four in particular are to be noted, namely:

a. Dresbach's syndrome, where the red corpuscles as seen either fresh or in films are elliptical instead of round, with but little bi-concavity.

b. Herrick's anemia, in which the red corpuscles are elongated and curved—'sickle-shaped'.

c. Malin's syndrome, or phagocytic anaemia or auto-erythro-phagocytosis; the red cells being found ingested by the leucocytes.

d. Clough and Richter's syndrome, in which the red corpuscles exhibit an extreme degree of auto-agglutination, i.e., tendency to rouleaux formation, sometimes without apparent cause; sometimes, though in minor degree, in cirrhosis of the liver, in certain fevers, and in trypanosomiasis.

ANGINA PECTORIS. It is impossible to give a definition of the term 'angina pectoris' that would satisfy everybody; this article limits itself to the more feasible task of discussing how to decide whether or not a pain in the chest is due to organic disease of the heart or aorta. This necessitates some examination of other causes of pains that are like those of heart disease. These are of two kinds: (1) Organic diseases of organs other than the heart; and (2) Functional disturbances of the cardiovascular apparatus.

The evidence that has to be weighed in coming to a decision is subjective as well as objective. On the one hand, there is the patient's own account of his pain, its nature, its site, the conditions under which it arises; on the other, the facts gleaned from an examination of his physical condition. True cardiac pain is usually referred to the middle line; it is said to arise beneath the sternum, sometimes behind the manubrium, occasionally beneath the ensiform cartilage, often beneath the middle part of the sternum. Sometimes it is felt in the arms, the side or back of the neck, the lower jaw, or between the

shoulders. Even when it is referred to these unusual sites it is also felt as a rule beneath the sternum.

If it is an arm that is affected, it is nearly always the left, the characteristic distribution being along the inner aspect of the whole arm to end in the little finger; but occasionally it is felt in the forearm only, even in the wrist only. Rarely both arms are involved; the right alone almost never. Pains of this kind may be wrongly set down to brachial neuritis.

Cardiac pain that is felt only in the epigastrium may easily be mistaken for that of gall-stones or indigestion; the more so because it is often accompanied by flatulence or even vomiting, with collapse. Often, also, cardiac pain follows a meal; or, rather, one should say that exertion is more likely to provoke cardiac pain when it is taken on a full stomach. These facts make diagnosis very difficult, and it is not surprising that the abdomen should have been opened because of pain that has afterwards proved itself due to heart disease.

Cardiac pain is variously described by its victims. The most constant of these descriptions implies a sense of pressure, like a heavy weight on the chest or a band fastened tightly round it, or the firm grip of a vice. It has an ominous flavour, which in its highly developed form is the 'angor animi' or sense of impending death which makes full-blown angina so terrible an experience. This combination of dull, heavy pressure with an instinctive realization of its serious import is very characteristic of anginal pain due to organic heart disease, and as different as can be from the pricking or stabbing pain over the heart that is so favourite a symptom of the functional cardiopathies.

Often the conditions under which the pain is experienced furnish a hint as to its cardiac origin. The most characteristic of these relationships is that in which the pain begins during exertion. Quiet walking on the level is found to be possible, but walking up-hill or against the wind, or hurrying against time, brings on a pain which pulls its subject up short. He has to stand still for a minute or two, pretending to look in at a shop window, before he can pull himself together for a renewed effort. Some patients find exertion much more likely to provoke pain when it follows a full meal. Others are sure to experience this kind of pain if they stoop to tie up a shoelace, for instance. Others, again, are waked by cardiac pain in the middle of the night. But, in general, it is the relation between exercise and the onset of pain that is characteristic.

Eruetation of wind is a frequent accompaniment of the anginal attack, and this helps the patient to console himself with a diagnosis of indigestion. As often as not, he does not complain of shortness of breath in the attack even if he is questioned on the point. Often, also, he will say that the pain does not make him feel faint, though he may confess to a sense of nausea. Salivation and polyuria are occasional features of the anginal spasm.

Before passing on to discuss the results of physical examination, we shall review the possibilities of error arising out of the patient's history. First, how may we be led to overlook the cardiac origin of a pain? The most likely mistake of this kind is that which makes the pain out to be due to some abdominal disease or disorder. The patient often says he is suffering from indigestion, and supports his diagnosis by a story of pain in the epigastrium accompanied by eructations and sometimes following meals. It is often difficult, sometimes impossible, to be sure that such a history is really that of cardiac disease and not of gall-stones or duodenal ulcer. The severest attacks of cardiac pain—those which we may suppose to be generally if not always due to coronary thrombosis—may closely imitate abdominal disease, for the pain is often epigastric and accompanied by vomiting and collapse. Pain limited to the left arm is apt to mislead. A man seen recently complained of nothing except bouts of severe pain in the left forearm, which was the site of a badly united fracture; and as he was an excitable person and showed no signs of cardiac disease, the pain was thought to be functional until a fatal attack proved it to be otherwise.

The other kind of error, in which pain due to other causes is thought to be cardiac, is at least as often made. There are three such causes that occur readily to the mind—gall-stones, dyspepsia, and functional disorders of the heart. In the first the pain is not related to exertion. In the second it is related to the taking of food. In the last the account given of the pain is not so precise; it is said to be pricking or stabbing, it is referred to the præcordium or the left costal border, and it is often accompanied by palpitations.

Physical examination may furnish positive information of the highest value. In the first place there may be evidence of gross organic disease of the heart, particularly of the first part of the aorta, cardiac syphilis and aortic atheroma taking the chief places. In the second group the arterial tension is high, but there is often nothing beyond the accentuation of the aortic second sound, and perhaps a little increase in the force and extent of the ventricular impulse, to suggest any affection of the heart; and it is to such patients that a reduction of hurry and worry is likely to afford most relief. The third group is that in which most mistakes are made, for it consists of elderly persons whose arteries are deteriorating, and in such persons the signs of cardiac degeneration are often trivial. Weakness of the heart sounds, a low blood-pressure, and a whitish colourlessness of the face are the only hints furnished by physical examination of the patient, and it is all too easy to ignore or undervalue such hints. It is in such circumstances as these that electrocardiography (*Figs. 71-73*) may offer valuable evidence of myocardial deterioration.

Fig. 71. The T wave is inverted, i.e., contrary to the direction of the principal ventricular peak R. When this is to be seen, as in the present instance, in leads I and II, it is usually associated with ventricular disease.

Fig. 72. The electrocardiogram is that of "right bundle branch block," i.e., transmission of the impulse from auricle to ventricle is made by the branch of the auriculo-ventricular bundle that goes to the right ventricle. This is shown by the lengthened P-R interval, and also the assumption of a left ventricular type of QRS movement.

Fig. 73. The QRS T part of the curve, that which represents ventricular systole, is greatly altered. It is lengthened in direction, and the main peak R is broken up into several smaller peaks. This is indicative of serious disease of the ventricular wall.

Figs. 71-73. ELECTROCARDIOGRAMS FROM PATIENTS WITH ANGINA PECTORIS.
P, Auricular systole; Q R S T, Ventricular systole.

(Kindly sent by Dr. John Han, Professor of Medicine in the University of Liverpool.)

The fact that the electrocardiogram is normal does not prove that the myocardium is normal, but abnormalities of the ventricular portions of the electrocardiographic curve afford solid confirmation of the suspicion that the pain is cardiac.

In a few instances pain of an anginal kind may be referred to the effect of certain general diseases on the myocardium. Thus, it may be experienced in the course of acute infections such as pneumonia, diphtheria, typhoid fever, acute rheumatism, and so on — infections which are known to injure the cardiac muscle; or in pernicious anemia; or, again, as a result of continued excess in tobacco. In any or all of these there may or may not be objective evidence of myocardial disease.

Again, there are persons whose description of the pain they have felt agrees closely with what we believe to be characteristic of cardiac pain; yet no physical signs of cardiac disease can be found. Here we must take into account the patient's temperament, his knowledge of medical matters in general and of the nature of the cardiac pain in particular, and so on. The effect of vasodilators in the relief of the pain is also worthy of consideration. If the pain recurs, the suspicion of a cardiac origin is strengthened. The most careful examination may end in a mistake, and there are cases on which, even though later events have shown that the pain was anginal, we look back in vain for the data that should have enabled us to make a correct diagnosis.

Finally, there are persons whose pain is very like that of cardiac disease, yet there

is nothing in the objective signs to show that such disease exists. Among these, two groups may be distinguished. First, there are those who have other symptoms of angio-spasm, Raynaud's disease, and the like, sufficiently striking to suggest that there is an angiospastic factor in the causation of the pain of which they complain; the theory being that just as peripheral arteries may contract and cause a local syncope, so also the coronary arteries may close spasmodically and induce a kind of cramp of the cardiac wall. Second, in some persons the relation of the pain to the taking of food, their liability to heartburn and other symptoms of acid dyspepsia, and the patient's own instinctive relation of the pain to his œsophagus, seem to justify the view that the pain is caused by some kind of spasmodic closure of the lower part of the œsophagus. Naturally hypotheses as speculative as these should not be adopted lightly, yet sometimes they afford a working basis for treatment of disorders that are otherwise inexplicable. If that treatment fails to relieve, the diagnosis must be reconsidered, and it is possible that in the meantime more definite evidence of cardiac disease may have presented itself.

There will always be a small residuum of patients whose pain cannot confidently be accounted for on the strength of one examination. Such people should be kept under observation until it is possible to make a positive diagnosis. Even with the utmost care mistakes will be made, and on the whole it is better to reassure the patient, and thus to risk an occasional loss of professional prestige, than to put one's own reputation first and frighten patients into needless invalidism.

Carey Coombs.

ANIDROSIS.—(See SWEATING, ABNORMALITIES OF, p. 803.)

ANKLE-CLONUS is best elicited when, the patient lying on his back, with his knee slightly flexed, the observer quickly, but not violently, dorsiflexes the foot, the hand being applied along its outer border in such a way as to keep it rotated well outward. The result, when ankle-clonus is present, is a series of rhythmical jerks at the ankle-joint *the contractions continuing as long as the pressure is maintained*. The last proviso is important, because it often happens that a few ankle-jerks are obtained, varying in number from two or three to as many as twenty or thirty, but gradually tailing off and ceasing, although the pressure on the sole is maintained. This is sometimes spoken of as a "tendency to ankle-clonus", but for clinical purposes it is not ankle-clonus at all, and indicates nothing more than hypersensitiveness of the nervous system, and not organic disease. Ankle-clonus, on the other hand, denotes changes in the corresponding crossed pyramidal tract, and it is to be expected in association with increased knee-jerk and extensor plantar reflex. Its chief value lies in determining between functional and organic exaggerations of the knee-jerk; the latter may be very brisk as the result of pure nervousness, but if it is associated with either an extensor plantar reflex or ankle-clonus, or both, the exaggeration is due to organic disease of the upper neuron, hemiplegic or paraplegic as the case may be. Whereas, however, the presence of maintained ankle-clonus is conclusive proof of an upper neuron lesion, the absence of such clonus does not exclude such lesion; ankle-clonus is not met with until there is a relatively large amount of lateral column change; it comes later, as a rule, than the extensor plantar reflexes.

Spontaneous ankle-clonus, not indicative of disease, but allied to chattering of the teeth, may result when one is chilled with cold, and then, sitting in a chair, raises the heel of the foot a little from the ground whilst the toes are still pressed to the floor; a little jerk to the knee will then send the calf muscles into rhythmic contractions which reproduce the phenomena of ankle-clonus, which continue as long as the foot and leg are kept in this one position, but cease as soon as the heel is put down to the ground again, or the foot is taken completely off the floor. This could not be mistaken for true pathological ankle-clonus, and the phenomenon ceases when one gets warmed up again at a fire or by taking exercise. It is a phenomenon of exposure to cold.

Herbert French.

ANOREXIA.—(See APPETITE, ABNORMAL, p. 58.)

ANOSMIA.—(See SMELL, ABNORMALITIES OF, p. 756.)

ANURIA—or suppression of urine—must be distinguished from *retention of urine*, in which urine is secreted from the kidneys but is retained in the bladder from some

lesion causing obstruction to the urethra, such as urethral stricture or prostatic obstruction in the male, or pressure or drag upon the urethra by a large pelvic tumour or a retroverted gravid uterus in the female, or without urethral obstruction in various forms of disease of the spinal nervous system affecting the lumbar centres. In retention of urine there is pain above the pubes, often constant and urgent desire to pass urine, and the distended bladder forms a tense, oval, dull tumour above the pubes in the middle line. In many cases a previous history of obstruction to the urinary flow will be obtained, whilst in others the involuntary dribbling of urine from the urethra from an over-distended bladder at once distinguishes the case from one of anuria, in which no urine reaches the bladder.

CAUSES OF ANURIA.

A. *Obstructive* :—

Calculus in kidney or ureter
Vesical carcinoma involving both the ureteric orifices

Uterine carcinoma infiltrating and obstructing both ureters
Large pelvic or abdominal tumours obstructing both ureters

B. *Non-obstructive* :—

In Renal Disease :—

Acute nephritis
Lardaceous kidneys
Tuberculosis of both kidneys
Polycystic disease of the kidneys
Suppurative pyelonephritis

after prostatectomy, or after perineal injury

After the sudden emptying of an over-distended bladder

In poisoning from mercury, lead, phosphorus, oxalic acid, cantharides, or turpentine

In severe collapse, either from severe injury or in association with severe febrile illnesses, such as dysentery, cholera, yellow fever

Other Causes :

Acute ascending nephritis
Reflex, after operations or trauma, especially after operations for piles,

Hysteria

Anuria may occur and be complete without any other symptom, and it is remarkable that in the obstructive forms, especially with calculus, anuria may be complete for several days without any other symptom—latent uræmia. In the non-obstructive forms anuria may be accompanied from the onset by the various symptoms of uræmia, such as vomiting, convulsive muscular twitchings, dyspnoea, and headache. In the obstructive form there may be total absence of any urine secreted, or a small quantity may be passed of low specific gravity, and containing very little urea or solids. Albumin is absent unless there be hæmaturia or cystitis, when pus may be present also. The patient may complain of aching in one or both loin regions, but, with the exception that no urine is passed, seems to be in ordinary health. The appetite is good and the mental state clear; but after a variable period, from seven to ten days, the patient becomes drowsy, the tongue dry, temperature subnormal, appetite deficient, and pupils small. There may be muscular twitching; the drowsiness gradually becomes deeper, without any true uræmic convulsions, and death may be postponed for as long as twenty days from the onset of the anuria. This sequence is very different from that seen when anuria occurs from non-obstructive causes, when there is frequently marked disturbance of the nervous system; headache and giddiness are followed rapidly by convulsions, delirium, and dyspnoea, with vomiting and small pupils, the patient rapidly becoming comatose and dying in a few days.

A.—OBSTRUCTIVE ANURIA.

Calculous Disease is the most frequent cause of obstructive anuria. It may occur at any age, but is commonest in men of about forty. Suppression of urine may arise from the impaction of a small calculus in the ureter of a kidney which is practically normal, or may be due to the total destruction of the renal secreting substance, which has progressed gradually and without marked symptoms. Between these two extremes there may be many stages, and the two conditions, namely, ureteric impaction and renal destruction, may exist at the same time. Clinically, it is rare for calculous anuria to arise from simultaneous blockage of both ureters by calculi; it is less uncommon to find that one kidney has been destroyed by previous disease, the ureter of the remaining organ then becoming obstructed by a stone. Exceptionally, the blockage of one ureter may cause reflex suppression of urine in the other kidney, especially if the function of the latter is impaired already

by disease : but in these cases the anuria is usually temporary. Calculous anuria may occur suddenly, and in patients who are apparently in good health, for it is no uncommon thing for a patient to go on in good health when he possesses only one functionally active kidney, the other having been destroyed by slow disease, or being absent : or there may be a history of previous lumbar pain, hæmaturia, pyuria, or the passage of calculi. At the onset of anuria there is usually pain in the loin region and along the course of the ureter of the side most recently affected ; it commonly lasts a day or so and then subsides, or it may last throughout the period of anuria. In addition, there is frequently a constant desire to micturate, although no urine is passed, or if the anuria is intermittent, urine of pale colour and low specific gravity, sometimes blood-stained, may be passed. If the anuria remains complete no other symptoms may occur for several days, a feature which is common to the obstructive forms of anuria, but is in marked contrast to the non-obstructive variety. After a period of anuria lasting from seven to ten days, the patient becomes drowsy, the tongue is dry, there is disinclination for food, and the general symptoms of uræmia may come on : but in many cases the patient may die before any uræmic symptoms occur. Thus, it is usual to speak of a *tolerant* and a *uræmic period* in obstructive anuria. The tolerant stage of obstructive anuria may be even further prolonged if the functional kidney be already hydronephrotic from previous intermittent obstruction, even to twenty days. The sudden obstruction to the urinary flow in a comparatively normal kidney causes complete suppression, whilst a partial or intermittent obstruction causes dilatation of the kidney. If such a kidney be the functioning organ, and become completely obstructed, the dilatation will increase : a lumbar tumour may be palpable. If there is pain on pressure over the kidney, or along the course of the ureter, the diagnosis is strengthened, or it may be decided to settle the diagnosis by immediate operation. In some cases in which one kidney has been destroyed gradually without pain, and anuria occurs, there may be great difficulty in determining which of the two kidneys is the functional organ which has recently become obstructed : in these cases it is a good rule to operate upon the side on which the pain has occurred most recently. If the patient is not too stout, palpation may detect a distinct area of pain over a calculus impacted in the course of the ureter ; or on careful rectal or vaginal examination a calculus impacted in the vesical end of the ureter may be felt. If the case is seen early, evidence of ureteric calculus may be obtained by the cystoscope, when the ureteric orifice of the obstructed side may be seen to be congested or ecchymosed. A skiagram of the renal and ureteric areas should be obtained if possible : large or multiple shadows in one renal area will suggest that that organ is functionally impaired or inactive, whereas a shadow in the line of the opposite ureter will indicate the immediate cause of the anuria. Operation upon the side of the recent pain may be urged strongly, when the kidney can be opened and drained, and opportunity taken to explore as much of the ureter as can be felt by the parietal incision and by catheterization from above.

Anuria from Vesical Carcinoma implies that either both ureteric orifices are involved in the disease, or that the ureteric orifice of the only functional kidney is implicated. The condition is uncommon as a pure obstructive anuria, for in most cases the kidneys are already the seat of changes due in part to the back-pressure and in part to sepsis, so that when anuria terminates a case of vesical carcinoma, it is more often due to renal disease than to ureteric obstruction. If the bladder has remained uninfected by septic organisms, the gradually increasing ureteric obstruction may first cause hydronephrosis, so that when the obstruction becomes complete the renal distention may increase quickly, and the symptoms of uræmia be delayed. In cases arising from vesical carcinoma it is very rare for the anuria to occur before symptoms of vesical growth are apparent, such as hæmaturia, pyuria, increased frequency, and pain on micturition ; but in the infiltrating type of carcinoma, hæmaturia and frequency of micturition may be absent for a long time. In all cases, careful vaginal or rectal examination will detect infiltration and thickening of the base of the bladder, and the growth can be seen through the cystoscope (*Fig. 288*, p. 354).

Uterine Carcinoma.—Anuria is frequent in the terminal stage of uterine carcinoma when the growth has extended into the cellular tissues of the broad ligament and involved the terminal portions of the ureters, or when the orifices of the latter are implicated in the direct infiltration of the growth into the bladder base. In the majority of cases dying

from uterine cancer, the kidneys are hydronephrotic, the renal pelvis dilated, or the renal secreting tissue sclerosed, apart from the frequent infection with septic micro-organisms. In all cases the growth has reached an advanced stage, but it has been recorded that anuria has occurred before the patient has complained of any symptom pointing to the uterine condition. These cases might simulate other forms of obstructive anuria, but the diagnosis would be apparent upon vaginal examination.

Pelvic or Abdominal Tumours, such as uterine fibromyomata or ovarian carcinomata, may cause anuria from direct pressure on the ureters, especially if a part of the tumour is impacted in the pelvic cavity. The cause of the anuria will be apparent on examination of the abdomen and of the pelvic organs.

B.—NON-OBSTRUCTIVE ANURIA.

Marked diminution in the amount of urine, or complete anuria may occur without obstructive lesion of the urinary apparatus, due in many instances to disease of the renal secreting tissues. In many of these cases the symptoms differ remarkably from those seen in obstructive anuria, in that the anuria is accompanied by symptoms of uræmia in a short time, and not after an interval of days as in the obstructive cases. Anuria may occur under certain toxic conditions, as in acute fevers, or in acute poisoning by mercury, lead, phosphorus, or turpentine; the history and accompanying symptoms of such cases are usually sufficient to point to the nature of the urinary suppression.

Anuria in Renal Disease. In *acute nephritis* anuria may occur early or after the disease is well established, and is usually accompanied by marked disturbance of the nervous system. The sudden onset of the disease after exposure to cold, or in the course of an acute specific fever such as scarlet fever, enteric, or pneumonia, or in hæmatogenous renal infections, associated with pallor, puffiness of the face and ankles, and slight pyrexia, together with the small amount of urine passed before the suppression becomes complete, are points all suggesting acute nephritis. If the urine has been tested before the onset of anuria it is often of reddish-brown colour from the presence of blood, and contains abundant albumin, together with renal, epithelial, and blood casts. In *chronic nephritis*, anuria may occur as a late symptom in the disease, and is occasionally preceded by a period in which polyuria is marked. Anuria in chronic nephritis is accompanied by prominent symptoms of uræmia, such as headache, giddiness, convulsions, stertor, and coma, and unless the flow of urine is re-established quickly, death ensues. The previous history of the case, high arterial tension, cardiac hypertrophy, retinal changes, and signs of back-pressure, with or without ascites and anasarca, will point to the nature of the anuria. In other diseases of the kidney, such as *lardaceous disease*, *suppurative pyelonephritis*, or *bilateral tuberculosis*, anuria may be preceded by general failing health, with loss of appetite, subnormal temperature, a dry brown tongue, headache, increasing pulse-rate, hicough, and attacks of dyspnoea; frequently there may be polyuria before suppression occurs. In these cases the anuria is terminal, the condition of the kidneys having been known previously. With the occurrence of anuria there may be great restlessness, with muscular twitching, loss of sphincteric control, convulsions, and a gradual lapse into coma.

Polycystic disease of the kidneys frequently terminates in anuria and uræmia, but the diagnosis of the disease has probably been arrived at previously. The symptoms resemble in a great measure those of chronic nephritis, with the exception that ascites and œdema of the extremities are uncommon. Headache, flatulence, and digestive troubles, sickness, and general lassitude are symptoms of renal inefficiency, whilst arteriosclerosis, a raised blood-pressure, a bilateral renal tumour, and a low-specific-gravity urine in increased quantity would suggest polycystic disease. Hæmaturia is the first symptom in not a few of these cases.

Anuria following Operations or Trauma. Anuria may occur in patients who have undergone an operation and who are the subjects of renal disease, or may occur occasionally even when no renal disease is present. Any extensive operation which involves a good deal of shock in a patient with renal disease, or in whom the kidneys have been subjected to back-pressure, as in uterine myomata, may succumb to anuria unless appropriate measures are undertaken; even an apparently trivial operation on the urinary organs may cause acute suppression of urine. This must be differentiated carefully from the

retention of urine in the bladder often seen after operations such as for hemorrhoids or for hernia. Acute suppression of urine may follow operations upon the lower urinary tracts, such as the passage of instruments or the performance of prostatectomy, or internal urethrotomy. Anuria is particularly liable to occur when a catheter is passed to relieve an over-distended bladder in a case of prostatic enlargement or urethral stricture, the kidneys being already distended from back-pressure or infected with septic processes, and it must be laid down as a golden rule that, if a catheter is passed in these cases, the urine must be withdrawn very gradually. Anuria following operations upon the lower urinary tract is diagnosed by the direct relationship between the operation and the onset of symptoms: by the rigors, pyrexia, and the profound prostration, rapidly followed by convulsive movements and coma.

Anuria may also occur in the severe *collapse* following an injury, in the late stages of *cholera* or *yellow fever*, and occasionally as a manifestation of *hysteria*. It may be simulated by a *malingeringer*.

R. H. Jocelyn Sican.

APHASIA. (See SPEECH, ABNORMALITIES OF, p. 769.)

APHONIA. (See SPEECH, ABNORMALITIES OF, p. 769.)

APPETITE, ABNORMAL.—Appetite may be: (1) *Increased*; (2) *Diminished* (3) *Perverted*.

1. **Increase of Appetite** sometimes occurs in cases of *hyperchlorhydria*. The general condition is then well maintained, there is usually pain or discomfort in the later period of digestion, relieved (temporarily) by the taking of more food. A test meal shows excess of hydrochloric acid.

In *diabetes*, especially in its earlier stages, there is often an abnormal craving for food; but in spite of large meals the patient wastes. Examination of the urine will establish the diagnosis.

Intestinal parasites (round-worms and tape-worms) are believed to cause excessive appetite in some cases. This is doubtful; but the point can be cleared up by examination of the stools for ova or by giving an anthelmintic and looking for the parasites themselves.

In some cases of *hysteria* an excessive appetite is present (*bulimia*). The patient is usually a young woman, and other stigmata of hysteria are present.

2. **Diminution of Appetite** occurs in many forms of dyspepsia, especially when associated with a lessened gastric secretion. Thus it is almost constantly present in *gastritis*, except, perhaps, in the acid form. If renal disease, advanced mitral disease, or cirrhosis of the liver are present, secondary gastritis may be diagnosed. If there is a history of the abuse of alcohol or tobacco, or of indiscretions in diet, or if there is a marked defect of the chewing apparatus, there is probably primary gastritis. The tongue will probably be furred, and a test-meal shows diminished acidity and probably an excess of mucus, but the examination of the stomach is otherwise negative. (See also INDIGESTION, p. 398.)

Loss of appetite is also an early symptom in cases of *gastric carcinoma*, and should elicit, especially in elderly subjects, to careful examination for other signs of that disease. There is frequently a special distaste for meat in such cases. (See INDIGESTION, p. 397.) In children a profound anorexia is sometimes an early symptom of *tuberculosis*; though many children pass through periods of eating only on persuasion without any organic lesion becoming apparent.

In hysterical young women complete disinclination for food (*anorexia nervosa*) is sometimes met with. The diagnosis is based upon the absence of other causes of the symptom, the presence of other signs of hysteria, and the history of mental or emotional shock. The loss of appetite in such cases may amount to a complete refusal of all food, and the patient may emaciate to a dangerous degree. Obstinate constipation is usually present as well. Allied to these cases is the loss of appetite which occurs in melancholic forms of *insanity*. In such a case delusions may be present.

3. **Perverted Appetite** may occur in the course of *pregnancy*, and is of no special significance. It is met with, too, in nervous, anæmic children, in whom it often takes the form of dirt-eating (*pica*). Here, also, it is not a sign of any diagnostic value. Perverted appetite is also a common occurrence in insanity; but other evidence of mental disturbance is always present as well.

Robert Hutchison.

ARRHYTHMIA. (See PULSE, IRREGULAR, p. 663.)

ASCITES, or the accumulation of serous fluid in the peritoneal cavity, is not a disease in itself, for it may be produced by a great variety of conditions. It is easy to determine its precise cause in some cases; in others it may be almost impossible to say during life what is the primary condition. One may discuss: (I) *Its physical signs*; (II) *How to distinguish it from other conditions which may simulate it*; (III) *A classified list of its causes*; (IV) *The chief points which will help in arriving at a correct differential diagnosis in a particular case*.

I. PHYSICAL SIGNS.

Inspection. The abdomen is distended uniformly, the degree varying with the amount of fluid. If the quantity is large, and its accumulation has been rapid, the abdomen is more or less globular, the umbilical region being the most prominent. The skin is tense and shiny, and there may be lineæ albicantes. If the quantity of fluid is large but its accumulation has been gradual, bulging of the flanks is more marked; the lower ribs may be pushed outwards and upwards, and the epigastric angle widened. If the quantity of fluid is small, only a slight bulging of the flanks may be noticed. The appearance of the abdomen depends a good deal on the position of the patient. If lying on one side, the most dependent part is the most prominent, owing to the fluid gravitating to that side of the abdomen. If the patient stands or sits upright, the hypogastric and iliac regions will be most bulged (*Fig. 74*). The umbilicus becomes stretched transversely and flush with the surface, or even protruded; it retains its position in the median abdominal line, and remains nearer to the pubes than to the ensiform cartilage. In tuberculous peritonitis and in some pneumococcal cases, the skin in its immediate neighbourhood may be reddened and œdematous, or there may be a fecal fistula here. In cirrhosis of the liver the veins around the umbilicus are said to be dilated, but the resultant so-called 'caput Medusæ' is rare. The superficial veins all over the abdomen and lower part of the chest may be dilated, the blood flowing in an upward direction, this reversal of the stream occurring mainly when the inferior vena cava is obstructed, either by the tension of the ascites or by something related to its cause. (See VEINS, VARICOSE ABDOMINAL, p. 908.) The abdominal respiratory movements may be absent or much diminished. The cardiac impulse may be displaced upwards and outwards. The legs, thighs, and scrotum may be œdematous, and so may the loins.

Fig. 74. A case of ascites from tuberculous peritonitis.

Palpation. The abdomen may be anything between quite flaccid and very tense. A fluid thrill may be obtained by placing the hand flat against one flank and gently flicking the other with the fingers of the other hand; the possibility of a thrill being transmitted in the abdominal wall should be eliminated by getting the patient or an assistant to place the side of his hand on the front of the abdomen, so as to stop transmission of the mural thrill.

If the liver or spleen has enlarged it sinks backwards, so that between these organs and the abdominal wall a layer of fluid is present: if the hand placed on the abdomen, in the right or left hypochondriac region as the case may be, is suddenly depressed, this fluid is displaced, and the surface of the enlarged organ can then be felt. This phenomenon of 'dipping' is almost pathognomonic of ascites.

Percussion. When the patient lies flat on his back the fluid gravitates to the posterior part of the abdomen, and the air-containing viscera float to the anterior part, so that the percussion note is resonant in front and dull in the flanks. As the fluid increases in quantity,

the line of dullness creeps forward from the flanks and upwards from the pubes, and keeps a concave upper border : in extreme cases the abdomen may be dull all over, particularly in children.

One of the most prominent physical signs of ascites is the effect produced on the percussion note by a change in the posture of the patient. If, after examining him lying on the back and finding dullness in the flanks and resonance in the front, he be turned on one side, the uppermost flank becomes resonant and the line of dullness on the other side rises nearer to the median abdominal line, owing to the fluid gravitating to the most dependent part. If only a very small quantity of fluid is present, the abdomen may be resonant all over when the patient lies on his back : but if he is percussed in the knee-elbow position, the umbilical region may be found to be dull.

In some cases, especially of tuberculous peritonitis, shortening of the mesentery is apt to be associated with the ascites : the intestines cannot then rise, and the result is dullness all over the abdomen, or in very exceptional cases dullness in front with resonance in the flanks.

Chronic peritonitis may cause the fluid to be loculated, through matting together of the intestines. The abdominal distention may then not be uniform, and change of posture may not alter the distribution of the dull percussion note.

Mensuration. The abdomen may be measured, fixed points being taken in front and behind, e.g., the umbilicus in front and the tip of the third lumbar spine behind : variations in the abdominal circumference afford some measure of changes in the amount of the ascites. The distance of the umbilicus from the ensiform cartilage, pubes and anterior superior iliac spines may also be noted. In ascites, the navel is nearly always nearer the pubes than the ensiform cartilage, and equidistant from the two anterior superior iliac spines when the patient lies flat on his back, whereas with large ovarian cysts which may simulate ascites the umbilicus may be nearer to one anterior superior iliac spine than to the other, and it also tends to become relatively nearer to the ensiform cartilage and further from the pubes than it normally is.

It is always important to examine the abdomen carefully after paracentesis : the cause of the ascites can often be discovered in this way, in the shape of tumours, or enlargements of organs, which were previously obscured by the tenseness of the abdominal wall.

II. DIAGNOSIS.

Ascites has to be distinguished from other conditions which may give rise to general abdominal distention, especially from : (1) *Tympanites* ; (2) *Ovarian and par-ovarian cysts* ; (3) *Gravid uterus, especially if with hydrops amnii* ; (4) *Distended bladder* ; (5) *Distention associated with obesity* ; (6) *Phantom tumour* ; (7) *Large abdominal cysts and solid tumours.*

1. **Tympanites** is distinguished from ascites by the following signs : The outline of coiled coils of intestine may be visible, and peristaltic movements may be noticed : there is no fluid thrill if precautions are taken to prevent a thrill being transmitted by the abdominal wall : the abdomen is resonant all over, both in front and in the flanks.

2. **Ovarian Cyst.** There may be a history of the enlargement of the abdomen having been noticed at an early date to be more on one side than the other, and to have arisen from the pelvis. The umbilicus may be nearer to the ensiform cartilage than the pubes, and nearer to one anterior superior iliac spine than the other. A fluid thrill may not be obtained far back in the flanks, but only in front of the mid-axillary lines. There is usually dullness in front, with resonance in the flanks. The outline of the cyst may possibly be noticed during the respiratory movements. On measuring the abdomen the greatest circumference is usually below the umbilicus, whereas in ascites it is generally at the umbilicus. A vaginal examination may reveal that the uterus is drawn upwards and that its mobility is impaired, whereas in ascites it is low down and movable. If paracentesis has been performed, the nature of the ovarian fluid is characteristic, being usually thick, tenacious, viscid, and of a brownish or greenish colour, whereas ascitic fluid is yellowish, limpid, and clear. Much difficulty arises when ovarian cyst and ascites are both present owing to infection of the peritoneum by secondary deposits from the ovary. Even without this, however, it is by no means always easy to distinguish between ovarian cyst and ascites when the abdominal distention has become extreme.

3. Gravid Uterus with Hydrops Amnii. In this condition it may be possible to make out the outline of the enlarged uterus; the tumour may vary in consistency as the uterine wall contracts and relaxes; on vaginal examination the cervix is soft and patulous and the uterus enlarged. There will be other signs of pregnancy, the characteristic condition of the breasts, fetal movements and heart-sounds, and the history of amenorrhœa. There will be dullness in the front of the abdomen, resonance in the flanks.

4. Distended Bladder. This may reach well above the umbilicus (*Fig. 627*, p. 815), in women most frequently as the result of a retroverted gravid uterus, in men over sixty from enlargement of the prostate, or in either sex from spinal-cord lesions such as compression paraplegia, lateral sclerosis, combined sclerosis, or tabes dorsalis, which may cause retention. The most important symptoms are incontinence of urine from overflow, and abdominal distention. There is generally a globular mass to be palpated in the middle line above the pubes and reaching up to the umbilicus or higher; it is dull to percussion in front, with resonance in the flanks. The passage of a catheter should clear up all doubt.

5. General Obesity may cause much abdominal distention. The mesentery, omentum, and abdominal wall may be so loaded with fat that it is difficult to make a satisfactory examination, and it may be almost impossible to determine with certainty the presence of even a moderate amount of fluid. With obesity the umbilicus remains as a deep pit; with ascites it becomes pushed forward to become flush with the surface, or even to protrude; with ascites, moreover, the umbilicus tends to become stretched laterally to form a transverse slit, whereas this is not the case in obesity.

6. Phantom Tumour. The abdomen may occasionally be so distended in women, especially at the time of the climacteric, that ascites, ovarian tumour, or pregnancy may be simulated when there is merely a phantom tumour. If an anæsthetic is administered it often disappears, the rigid abdominal wall becomes flaccid, and it can be determined whether fluid in the peritoneal cavity or any abdominal tumour is present or not.

7. Large Abdominal Cysts may occasionally simulate ascites, e.g., hydronephrosis, pancreatic cyst, cyst of the lesser omental sac, retroperitoneal cyst, or hydatid cyst; they do not, however, cause uniform distention of the abdomen as a rule. They are most likely to be mistaken for simple chronic peritonitis in which local collections of fluid have arisen from matting together of the intestines. Hydronephrosis may be distinguished by its position, by the way it bulges back into one loin, and by the fact that it may vary in size, a decrease being associated with an increase in the amount of urine passed. Pancreatic cyst may be differentiated by its position in the upper part of the abdomen and by its more or less circular outline; if paracentesis abdominis has been performed, the character of the fluid and the presence in it of peptonizing and starch-digesting ferments would point to the nature of the disease.

III. CAUSES.

Having made up one's mind that the general abdominal distention is due to fluid in the peritoneal cavity, one must next differentiate the cause of the ascites. The following is a classified list:

1. Diseases of the Peritoneum:—

Non-suppurative acute peritonitis	Malignant peritonitis, generally secondary to
'Simple' chronic peritonitis	a primary growth elsewhere
Tuberculous peritonitis	Hydatid cysts in the peritoneal cavity

2. Obstruction to the main Portal Vein, by:—

Non-suppurative thrombosis

Enlarged portal lymphatic glands:—

Malignant	Tuberculous
Lymphadenomatous	Lymphatic leukæmic

Tumours of adjacent organs, such as:—

Liver	Stomach	Suprarenal capsule
Pancreas	Duodenum	
Kidney	Colon	

Rarities such as aneurysm of the hepatic artery

3. Diseases of the Liver :—

Cirrhosis

Perihepatitis, really part of chronic simple peritonitis

Carcinoma

Sarcoma

Syphilis

Hydatid disease

Abscess

Doubtful causes if the lesions are confined to the liver: i.e., if there is ascites, it is probably not due to the carcinoma, etc., in the liver, but to concomitant affection either of the peritoneum or of the portal lymphatic glands

4. Obstruction of the Inferior Vena Cava above the Hepatic Veins, by :—

Thrombosis

Chronic mediastinitis

Mediastinal growth

5. Chronic Failure of the Right Heart ('backward pressure'), the result of :—

Valvular disease :—

Mitral stenosis

Mitral regurgitation

Aortic stenosis or regurgitation, rheumatic or syphilitic, with secondary mitral regurgitation

Congenital pulmonary stenosis (rarely)

Adherent pericardium

Chronic lung affections, especially :

Emphysema

Recurrent bronchitis

Fibroid lung

} Generally associated

Chronic myocardial affections :—

Fatty degeneration

Fatty infiltration

Fatty superposition

Fibroid heart

Primary alcoholic heart

Chronic high blood-pressure :—

Red granular contracted kidneys

Pale granular contracted kidneys

Arteriosclerosis

'Simple' hyperpiesis

6. Bright's Disease. In Bright's disease ascites may be caused in at least four different ways—namely, as the result of :—

Part of a general dropsy

Acute peritonitis

Chronic peritonitis

Secondary to hypertrophy and dilatation of the heart, followed by failure of compensation

7. Severe Anæmias, in which the ascites is usually the result of acute, subacute, or chronic intercurrent peritonitis, as in :—

Splenedullary leukaemia

Lymphatic leukaemia

Hodgkin's disease

Pseudoleukaemia infantum

Splenic anaemia

Pernicious anaemia

Familial splenomegaly

Acholuric jaundice

Aplastic anaemia

Malaria

Egyptian splenomegaly

Kala-azar

8. Lymphatic Obstruction, especially to the thoracic duct or receptaculum chyli (generally 'chylous' ascites), as the result of :—

Severe injury to the abdomen or chest

Elephantiasis

Retroperitoneal sarcoma

Mediastinal sarcoma

9. Semi-starvation, or rather long-continued bare maintenance of life on famine dietary, inadequate in variety and in amount.

10. Polyorrhomenitis or Multiple Serositis, a state of affairs in which, often without apparent cause, the patient develops recurrent inflammatory exudates into all the serous cavities—chronic peritonitis with ascites, pericarditis with effusion, pleurisy with effusion—yet may survive for years. Some of these cases would appear to be tuberculous, others syphilitic, but quite often the cause is never discovered in spite of repeated tapplings.

IV. DIFFERENTIAL DIAGNOSIS.

If ascites is the only fluid accumulation present in the patient; if, although there is also swelling and œdema of the legs, the ascites is known to have appeared first; or if the ascites is out of proportion to dropsy elsewhere, it is probably due either to some form of peritonitis, to portal obstruction from thrombosis of or pressure on the portal vein, to cirrhosis of the liver, or to obstruction to the receptaculum chyli.

If it is associated with general anasarca, that is to say, with œdema of the legs, body, and face, perhaps even of the scalp, and possibly with other serous effusions, the probable cause is acute, or acute on chronic, Bright's disease.

If swelling and œdema of the legs were noticed first and the ascites followed, heart failure from one of the causes in Group 5, or obstruction of the inferior vena cava above the hepatic veins, or one of the severe anamias, would be the most likely cause ; it is important to remember, however, that in the slighter cases, or in those of long standing, the patient is often uncertain which swelled first, his legs or his abdomen, and his statements on the point may be misleading.

If jaundice is associated with the ascites, it points to some form of portal obstruction as the cause, either cirrhosis of the liver, or, if the jaundice is intense, to some actual pressure on the portal vein and common bile-ducts, generally due to malignant disease.

If enlargement of the liver is associated with the ascites this may be due to carcinoma, sarcoma, cirrhosis, perihepatitis, hydatid disease, hepatic abscess, syphilis of the liver, or to nutmeg change the result of backward pressure from chronic heart or lung disease.

If the ascites is associated with multiple abdominal tumours it suggests tuberculous or malignant peritonitis, secondary proliferating ovarian cysts, or in rarer cases hydatid disease.

1. Diseases of the Peritoneum. — *Acute Non-suppurative Peritonitis* is an acute inflammation of the peritoneum analogous to acute 'simple' pleurisy with serous effusion. One seldom speaks of ascites, however, in connection with acute infective peritonitis such as requires urgent laparotomy ; and it is difficult to draw a decided line between acute peritonitis in which the fluid should be called ascites and other conditions of acute generalized peritonitis to which the term would not be applied. There are, however, cases in which acute serous effusion due to non-suppurative peritonitis occurs in acute and chronic Bright's disease ; of acute tuberculous peritonitis almost simulating general suppurative peritonitis ; whilst pneumococcal and gonococcal peritonitis may be acute in onset and yet take the form of an ascitic effusion, recovery occurring without the necessity for laparotomy. It is probably a question of the dose of the micro-organism that affects the peritoneum, and it is by no means impossible that, whereas the perforation of a gastric ulcer, duodenal ulcer, dysenteric, typhoid, or tuberculous ulcer of the intestines, or leakage from a pyosalpinx, an appendicular abscess, stercoral ulcer of the colon, or a perirectal or prostatic abscess, generally gives rise to acute general peritonitis which would prove suppurative if it were not operated on, the same conditions may in some cases lead to a slighter affection with a severe but non-suppurative ascitic effusion ending in spontaneous recovery. Whether laparotomy is indicated or not in any given instance must depend upon the individual circumstances of the case ; but it is much safer for the patient to be operated upon for acute non-suppurative peritonitis of the type of which we are now speaking than for general suppurative peritonitis to escape operation.

Simple Chronic Peritonitis is a chronic inflammation that is not tuberculous or malignant. It may follow simple acute peritonitis, but its two commonest causes are : a former tuberculous peritonitis from which the tubercles have disappeared ; and the chronic inflammation which results from repeated paracentesis abdominis for any other variety of ascites. The latter is important ; it sometimes happens, in a heart case for instance, that both œdema of the legs and ascites have been prominent symptoms, paracentesis abdominis being indicated on account of the cardiac distress ; the tapping of the abdomen may have had to be repeated several times, and yet ultimately the cardiac compensation has been restored, the patient's general condition becoming quite good and the œdema of the legs disappearing ; yet in spite of this general improvement, ascites may still persist and require further tapping at intervals. In such a case, whereas at first the ascites was due to backward pressure from the failing heart, it ultimately becomes due to chronic peritonitis, the result of the repeated tapplings. It is usually associated with perihepatitis, which indeed is only one of the local manifestations of chronic peritonitis. Even when all inflammation has ceased, the great thickening of the peritoneum over the diaphragm, liver, and spleen may have blocked up those pores through which the peritoneal secretions naturally drain away, so that the fluid keeps on re-accumulating, and necessitates repeated tapping, which in some cases has been performed over three hundred times. The peritoneum becomes thickened generally and the intestines bound down and matted together. There may be local or general abdominal distention, depending on whether loculi are formed or not by the adhesions. On account of the shortening of the mesentery and matting together of the intestines there may be dullness all over the abdomen, so that this form of ascites is particularly liable

to be mistaken for ovarian cyst or tumour. Albuminuria is frequent on account of interference with the renal circulation, and there may even be a few tube-casts: there may or may not be actual renal disease, but this should not be diagnosed from the albuminuria unless there is also high blood-pressure, retinitis, or other confirmatory sign. Abdominal pain is generally slight, and although there may be vomiting or constipation, there is usually neither.

Tuberculous Peritonitis.—This is the most common cause of ascites in children. There are several varieties, of which the following may be distinguished:

i. The acute ascitic form, which may simulate acute general peritonitis due to perforation of a viscus.

ii. The subacute or chronic ascitic form: the peritoneum may be studded all over with miliary tubercles without any caseous masses. The physical signs are those of ascites

Fig. 75. Temperature chart in a case of tuberculous peritonitis of the acute type.

without any abdominal tumour, and it is not difficult to mistake it when it occurs in an adult for cirrhosis of the liver or for malignant peritonitis, especially that form which is secondary to ovarian tumour. In a child, the occurrence of ascites without oedema of the legs at once suggests tuberculous peritonitis: in an older person tuberculous peritonitis is much less common.

iii. The omentum may be contracted and thickened from infiltration with caseous or fibro-caseous material, and a hard abdominal tumour simulating an enlarged liver may be felt. It may be distinguished, however, by the resonant percussion note between it and the costal margin, and the liver edge may be palpable above and distinct from the omental mass which simulates it. Ascites in cases of this kind is generally less in amount than in the miliary tuberculous form.

iv. The intestines may be matted together and the adhesions thickened and infiltrated with tuberculous deposits, so that the peritoneal cavity may be divided into several loculi of fluid, the abdominal distention being not uniform, and paracentesis only removing part of the ascites.

v. The mesentery may be thickened and contracted, and the intestines bound down to the posterior parts of the abdominal cavity, so that if there is ascites there will either be dullness all over the abdomen, or dullness in front with resonance in the flanks, suggesting ovarian cyst rather than tuberculous peritonitis. After paracentesis, a more or less defined, irregular, deeply situated tumour may be felt.

vi. When the caseation affects the mesenteric glands in particular, multiple irregular tumours are felt, sometimes but not always associated with ascites.

vii. Occasionally local thickenings in the abdominal wall are to be felt as the result of subperitoneal inflammatory deposits, especially in the neighbourhood of the umbilicus, a condition which may often be mistaken for rigid contraction of the recti muscles or for disease of the parietes rather than of the peritoneum: there may be reddening of the skin all round the umbilicus, or a spontaneous fecal fistula here, either of which are strongly suggestive of tuberculous peritonitis, particularly in a child.

It will naturally depend upon the acuteness of the tuberculous process whether there will be pyrexia or not, and whether there will be abdominal pain and tenderness. In the caseous varieties, whether of the glands, omentum, mesentery, or abdominal wall, pain and tenderness are the rule, and the temperature generally rises to 101° F. to 104° F. each evening (*Fig. 75*). When the active tuberculous process has become quiescent there may still be ascites, though the temperature is subnormal. When paracentesis is performed, it is advisable to inject some of the fluid into a guinea-pig, to see if the latter develops general tuberculosis during the succeeding six weeks: or in a shorter time if the guinea-pig has been treated previously by recurrent exposures to X rays, which accelerate the reaction. The nature of the case may sometimes be suggested by the presence of tuberculous lesions elsewhere in the patient's body: for instance, in the spine, kidney, a joint such as the hip or knee, glands in the neck, or lupus, though very often tuberculous peritonitis is the only objective lesion.

Ascitic Fluids. It has been stated that chemical analyses of ascitic fluid often afford material assistance in arriving at a diagnosis of its cause: but in practice only the broadest conclusions can be drawn. The higher the specific gravity, the larger the percentage of albumin, and the greater the tendency to spontaneous coagulation, the more definitely can one conclude that the condition is an inflammatory exudate: e.g., specific gravity 1025, twenty parts per thousand of albumin, with a spontaneous coagulation. The lower the specific gravity, the smaller the percentage of albumin, and the more definite the absence of spontaneous coagulation, the more likely is the condition to be a non-inflammatory transudate: e.g., specific gravity 1005, five parts per thousand of albumin, and no spontaneous coagulation. There are, however, many intermediate cases in which chemical investigation of the fluid leaves one in doubt as to whether the condition is inflammatory or not.

It has also been stated that differential analyses of the proteins are helpful, notably as to whether there is more globulin or more albumin present: but it is doubtful whether this really is so.

Microscopical examinations are more valuable than chemical. The centrifugized deposit should be examined under the high power: when inflammatory it may exhibit many leucocytes, polymorphonuclear cells predominating in acute conditions, small lymphocytes in subacute or chronic affections such as tuberculous peritonitis: peritoneal cells in cases of inflammation: and occasionally the diagnosis is clinched by finding actual fragments of new growth or hydatid hooklets (*Fig. 76*). The deposits may also be stained for bacteria, and sometimes tubercle bacilli, streptococci, staphylococci, gonococci, or pneumococci may be found. When investigating ascitic fluid bacteriologically, however, it is better to resort to cultural or inoculation methods than to rely solely upon films prepared from the deposit.

Fig. 76. Echinococci or hooklets.

Cancerous peritonitis usually occurs in patients over forty, and the growth is practically always secondary. Primary carcinoma of the peritoneum is very rare, and it is usually colloid and not associated with ascites. In secondary cases the omentum may be thickened and infiltrated, the umbilicus fixed, the urachus palpably infiltrated, and nodules and masses may develop all over the peritoneum. Rapid emaciation and cachexia are the rule. A large quantity of fluid may be present, and if it is blood-stained at the first tapping this is very suggestive of malignant disease. Ascites may be the first and only evidence of growth, and it may be mistaken for that of tuberculous peritonitis or cirrhosis of the liver, especially when the abdominal distention is so marked that no nodules can be felt. Evidence of a primary growth should always be looked for with care, especially in connection with the stomach, pancreas, colon, rectum, or ovaries. Rectal examination should never be

omitted, and if need be the sigmoidoscope may be used. It should not be forgotten that useful indication of intra-abdominal malignant disease is sometimes afforded by enlargement of the left supraclavicular lymphatic glands by secondary deposits (*Fig. 77*).

There is one variety of secondary malignant peritonitis which merits special mention—namely, that which may result from a proliferating papillomatous ovarian cyst. The malignancy of the latter is sometimes relative, so that although there may be thousands of papilloma deposits on the peritoneum, causing ascites that may need tapping scores of times at short intervals, there may be no other secondary deposits anywhere. The diagnosis may be made as the result of careful vaginal examination, or by finding fragments of the

malignant papillomata in the ascitic fluid, or perhaps the case may be regarded as chronic 'simple' peritonitis until the abdomen is opened.

Hydatid cysts in the peritoneal cavity may be primary, but more often they are secondary to hydatid disease of the liver. The malady is rare in this country, though commoner in Australasia and elsewhere. The patient is generally an adult and the diagnosis is often obvious, though sometimes it may be very obscure. There may be a large globular tumour in the liver, rarely giving the typical hydatid thrill; there may be *Eosinophilia* (p. 271), and an investigation of the blood serum in special laboratories may show the specific hydatid serum reaction. In some cases in which there are hydatid cysts associated with ascites it is possible to make the diagnosis by rectal examination; one has felt globular bodies about the size of grapes in front of the anterior rectal wall, and when these have been pressed upon to investigate them more fully, they have slipped away from under one's finger through being pushed up into the ascitic fluid; after waiting a moment the finger has felt them come back into Douglas's pouch. Similar mobility of spherical masses in the ascitic fluid may be

Fig. 77. Enlargement of the left supraclavicular glands in a case of abdominal malignant disease (carcinoma of the sigmoid colon). A, Enlarged glands containing secondary growth.

noted elsewhere—for instance, in an iliac fossa. The ultimate diagnosis depends upon the detection of daughter cysts, hooklets (*Fig. 76*), or scolices (*Figs. 623a, 623b*, p. 806), in the fluid obtained by paracentesis or by laparotomy. It is important to bear in mind, however, that the absence of hooklets does not exclude hydatid disease, the cysts sometimes being sterile, and in that case not producing hooklets.

2. Obstruction to the Main Portal Vein.—This is most commonly due to *enlargement of the portal lymphatic glands* by secondary deposits of malignant disease; it is common for the main bile-ducts to be obstructed at the same time, so that an increasing depth of jaundice accompanies the ascites. When there are masses of secondary growth in the liver associated with jaundice, or ascites, or both, it is seldom that the hepatic masses are themselves responsible for the symptoms, these being more often due to the associated deposits in the portal lymphatic glands. The diagnosis is made on discovering a primary growth, more often a carcinoma than a sarcoma. It is much rarer for the lymphatic glandular enlargement to be lymphadenomatous, tuberculous, or due to lymphatic leukaemia. If ascites were a prominent symptom in any of these conditions it would be regarded as consequent on affection of the peritoneum rather than on obstruction to the portal vein, unless there were deepening jaundice at the same time. In the latter case malignant disease would be simulated. General enlargement of the lymphatic glands in the axillae, groins, and neck, with or without evidence of enlargement of those in the thorax or abdomen, together with enlargement of the spleen, would suggest either lymphadenoma or lymphatic leukaemia; the absence of positive blood changes would render the former more likely, for in lymphatic leukaemia there is more or less considerable leucocytosis with a great relative increase in the small lymphocytes up to 90 per cent or more (p. 34). Only in very rare cases do tuberculous portal

glands cause ascites, and when they do the diagnosis must be one of guess-work only, unless in association with definite tuberculous peritonitis there were jaundice suggesting obstruction to the common bile-duct and to the portal vein at the same time.

Thrombosis of the portal vein may be suppurative, in which case there is no ascites, but a pyrexial condition with rigors and possibly jaundice, diagnosed as a rule only when there has been some definite inflammatory focus in the portal area, such as appendicitis, which might lead to infection of the portal vein. Primary thrombosis of the portal vein is rare, and its diagnosis can seldom be more than guessed at. It leads to marked ascites, possibly with simultaneous increase in any tendency there may be to piles, and without evidence of tuberculous or malignant disease of the peritoneum or cirrhosis of the liver. It is by a process of exclusion that the diagnosis of portal vein thrombosis might be arrived at, especially if the ascitic fluid withdrawn by paracentesis, when examined chemically, were found to contain a relatively very high proportion of coagulable proteins without any particular tendency to spontaneous coagulation, and without those polymorphonuclear cells or lymphocytes that would be found if the high percentage of protein were due to the ascites being inflammatory.

Tumours of adjacent organs seldom obstruct the portal vein enough to cause ascites without presenting other symptoms which suggest the diagnosis. Sometimes, however, unless the tumour can be felt, great difficulty may be experienced in determining the nature of the case. Carcinoma of the pancreas may be accompanied by glycosuria and the passage of fatty stools, together with deepening jaundice, progressive enlargement of the gall-bladder, and a positive CAMMIDGE'S PANCREATIC REACTION (p. 128). On account of the relation of the tumour to the aorta, marked transmitted pulsation may be felt in it, and by inflating the stomach it may be demonstrated that the tumour lies posterior to the latter. Renal tumours may be difficult to distinguish from enlargement of the liver when they are big; but they are generally associated with ALBUMINURIA (p. 4), HÆMATURIA (p. 347), or PYURIA (p. 715); in cases of doubt a cystoscopic investigation accompanied by ureteric catheterization may be needed to settle the question. Carcinoma of the stomach, duodenum, colon, or suprarenal capsule would be suggested by the position of the mass, or by the gastric or intestinal symptoms; if there were ascites accompanying them, it would generally be due not to the primary tumour, but to secondary deposits either in the peritoneum or in the portal lymphatic glands.

Aneurysm of the hepatic artery is a pathological curiosity, though in recorded cases it has produced ascites and jaundice. The commonest cause of aneurysm of the hepatic artery is fungating endocarditis with embolism.

3. Diseases of the Liver.

Cirrhosis of the Liver. When ascites is the result of this condition, the diagnosis is sometimes easy on account of the history of chronic alcoholism, and possibly a history of former hæmatemesis, melæna, or jaundice. There may also be acne rosacea and telangiectases on the cheeks or even a bottle-nose, a furred and tremulous tongue, a history of morning sickness, cramps in the legs at night, nausea, loss of appetite especially for breakfast, epistaxis, perhaps the presence of distended veins round the umbilicus, hæmorrhoids, enlargement of the liver, the surface of which is hard and rough and the edge irregular and perhaps beaded, enlargement of the spleen, icteric tinge of the conjunctivæ, and a peculiarly sallow, slightly pigmented facies, which is almost characteristic in the later stages of the malady. Cirrhosis is a slowly progressive disease, sometimes extending over twenty years or more, producing a large, smooth, unilobular cirrhotic liver with jaundice and a tendency to hæmatemesis in its earlier stages; but later a small liver in which, in addition to the unilobular fibrous tissue, there has developed a much coarser multilobular meshwork which, by progressive contraction, has led to the previously large, smooth organ becoming smaller, rougher, and harder, until it may sometimes be so small as to be no longer palpable. Only in the very last stage does it produce ascites. People have been known to be total abstainers for as long as eighteen years or more after the first symptoms of cirrhosis have developed, and yet to die with a granular, contracted, 'hob-nail' liver and ascites.

Perihepatitis. A case of cirrhosis of the liver seldom survives long after it has first become necessary to tap the abdomen, and when paracentesis abdominis has to be performed more than once or twice in a case supposed to be cirrhosis, this points to the diagnosis being wrong, the case being one, not of cirrhosis, but of perihepatitis. This is not always so,

however, for it happens sometimes that even when the ascites was originally due to cirrhosis, the repeated tapping produces perihepatitis, the greatly thickened capsule of the liver being the result of multiple tapplings for what was at first cirrhotic ascites. It is exceedingly difficult to be certain of the diagnosis of simple perihepatitis: the condition is really only part of a chronic peritonitis. The capsule of the liver becomes much thickened, and it contracts and distorts the organ, and rounds the edge, or else turns it up or under, in a way which is characteristic. It is only if this curled-under or turned-up edge can be recognized that perihepatitis can be diagnosed with certainty. Syphilis may be the cause in some cases.

Ascites associated with *carcinoma* or *sarcoma of the liver* is usually accompanied by intense jaundice, and there is always doubt as to whether these symptoms are not due rather to coincident affection of the portal lymphatic glands than to the deposits in the liver itself. The latter becomes much enlarged, very hard, the edge often coming well below the umbilicus. Probably the largest livers that occur are due to secondary carcinoma or sarcoma. They may reach a weight of 22 lb. or more. Besides being very hard, the liver may be tender, and umbilicated nodules may be felt on its surface. Primary growth of the liver is exceedingly rare, and though it leads to progressive and deepening jaundice, it does not often produce ascites. Secondary growth is so much more common that it is important to look for the primary growth elsewhere with great care before primary growth in the liver is diagnosed. Retinal and rectal examination should not be omitted: and Cammidge's pancreatic reaction (p. 128) should be tested, in case the primary growth be in the pancreas.

Syphilis may produce local peritonitis over a gumma: it may also lead to general chronic peritonitis and thus to ascites. The diagnosis is made upon the history, upon the signs of syphilis elsewhere, and upon Wassermann's serum reaction.

Hydatid disease of the liver seldom of itself causes ascites, though it may be associated with coincident affection of the peritoneum with ascites.

Abscess of the liver occurs more often without ascites than with it: but by infecting the capsule of the liver and thus producing local acute peritonitis it may lead to serous exudation and ascites unless the perihepatitis becomes localized by adhesions.

We may now pass on to consider those cases in which, if the history is correct, there has been swelling of the legs before, or at any rate not later than, swelling of the abdomen: and if one follows the classification as given on pages 61 and 62, one comes next to:

4. Obstruction of the Inferior Vena Cava above the Hepatic Veins. This is rare, and will seldom be diagnosed unless there is either: (a) Clear evidence of extension of *thrombosis* to the inferior vena cava from a previous thrombus in one leg, associated with extension of oedema up the back, followed by albuminuria and perhaps hæmaturia when the renal veins are involved, and then by ascites, together with varicose distention of the abdominal veins and reversal of the blood-stream in them: or (b) A history or the physical signs of *chronic mediastinitis*, which generally results from recurrent attacks of pleurisy, pericarditis, especially rheumatic, or of *intrathoracic new growth*, which is distinguished from chronic mediastinitis by the shorter history and by the X-ray appearances. (*Fig. 120*, p. 136.) (See VEINS, VARICOSE ABDOMINAL, p. 908; and VEINS, VARICOSE THORACIC, p. 910).

5. Chronic Failure of the Right Side of the Heart (Backward Pressure). Ascites as the result of backward pressure in chronic heart and lung disease is nearly always preceded by swelling and oedema of the legs. Careful examination of the heart and lungs, a history of acute rheumatism, or of recurrent winter cough, or an abundant and offensive periodic expectoration, may suggest valvular disease of the heart, chronic bronchitis and emphysema, or fibroid lung with or without bronchiectasis, to account for the ascites. Nutmeg liver also results in these cases, the enlargement varying to some extent with the degree of heart failure, the surface of the organ being smooth, tender, with a well-defined edge which may reach below the level of the umbilicus in the right nipple line, and sometimes pulsating synchronously with the heart. The urine is apt to contain albumin, and when the heart failure has reached an advanced degree it may be exceedingly difficult to say whether it is due to primary valvular disease, primary lung disease, primary kidney disease, primary arterial disease, or to primary affection of the muscle of the heart (see p. 17). The importance of casts in the urine in the differential diagnosis has been referred to under ALBUMINURIA (p. 8), where the significance of the blood-pressure, of retinal changes, and so forth, are also discussed.

The valvular heart lesion most apt to be mis-diagnosed in connection with ascites is *mitral stenosis* ; for by the time the heart failure has reached a sufficient degree to cause ascites, characteristic bruits, especially the presystolic, become no longer audible in many cases. The heart beats very rapidly and irregularly from auricular fibrillation, and no bruits may be audible at all. Mitral stenosis may still be suggested by the characteristic facies (*Fig. 78*), with its yellowish pallor of the forehead and around the nose and mouth, with bright or dark red coloration of the lips and over the malar bones and upper portions of the cheeks ; or by the history of acute rheumatism or chorea, though absence of such a history by no means excludes valvular heart disease. It may, however, be impossible to say whether there is mitral stenosis or not until the patient has been kept in bed, given

Fig. 78. The facies in mitral stenosis, showing the typical malar flush and deep-red lips, with yellowish pallor of the forehead, nose, and circumoral region.

digitalis, and watched for a week or more, until there is some degree of recovery of the cardiac compensation ; by which time the characteristic bruits of mitral stenosis very often return with the increasing force of the heart's beat.

Some of the hardest of heart-failure cases to diagnose with certainty are those due to *chronic affections of the myocardium* or to *adherent pericardium*. In each case the diagnosis is arrived at mainly by a process of exclusion. Chronic myocardial degeneration seldom occurs in young people, or at any rate it is much commoner in middle life and later. The symptoms are those which are common in all varieties of chronic heart failure (p. 247), whatever the cause of the latter. There may or may not be the systolic bruit of mitral regurgitation, or an aortic systolic bruit due to atheroma of the aortic valves, but upon the whole the physical signs do not suggest valvular disease ; the urinary changes and the absence of casts do not suggest nephritis or granular kidney ; the blood-pressure may not suggest arteriosclerosis ; the lung signs do not suggest bronchitis and emphysema, or fibroid lung ; so that some myocardial affection is all that is left to diagnose. If there is a history of the

drinking of much alcohol, particularly beer, *primary alcoholic heart* may be suspected. *Fatty superposition* would be suggested if there were general obesity with shortness of breath on ordinary exertion : whilst overloading of the surface of the heart seldom occurs without some *fatty infiltration* at the same time. *Fatty degeneration* is more likely after a long illness, or chronic poisoning by phosphorus, arsenic, or lead, or by the toxins associated with severe anemias, such as pernicious or aplastic anemia. *Fibroid heart* is very difficult to distinguish from fatty heart, but it is the more likely in a syphilitic patient, particularly if the patient is not obese and if there is syphilitic aortic regurgitation or angina pectoris. With any of these changes it is unlikely that the dimensions of the heart remain normal : its increased size may be indicated by the displacement of the cardiac impulse outwards to or beyond the left nipple line : or by the increase in the area of precordial impairment of percussion note : no physical method of examination, however, is so certain in determining the size of the heart as is screening with the X rays, with which the transverse diameters of the shadows of the ventricles, auricles, and aortic arch may be measured with a ruler. The ventricles should not exceed $5\frac{1}{2}$ inches in a woman, or 6 inches in a man, in maximum transverse width, but when they are affected by myocardial or other disease they may be as much as 9 inches across without the fact being particularly obvious until X-ray screening is resorted to. Electrocardiographic records may also be of great assistance in determining the existence of myocardial changes (p. 53), but not in deciding between fatty and fibroid.

Adherent pericardium is not in itself an explicit term, for there are three different conditions which come under the one heading. There may be : (1) Adhesions between the parietal and visceral layers of the pericardium ; (2) Adhesions between the parietal pericardium and the structures around it, particularly the pleuræ, diaphragm, and chest wall ; or (3) Adhesions both of the parietal to the visceral layer of pericardium and of the parietal layer to the structures outside it—really a form of chronic mediastinitis. It is clear that the physical signs will differ according to which of these three things is present. That which ought to be implied strictly by the term *adherent pericardium* is adhesion of the parietal to the visceral layer, without any other adhesions whatever, and of this condition there are no positive physical signs at all, nor need there be any symptoms. The diagnosis is generally made by guess-work, the patient being known to have had pericarditis, or being suspected of having had it because of having suffered from acute rheumatism with severe complications, and the heart now being found much larger than it ought to be in proportion to the apparent valvular disease as indicated by the bruits. It is common, however, for the parietal and visceral layers of pericardium to be universally adherent without the heart being big, and without there being any ill effects at all, the condition being met with post mortem in patients who die of something quite different. It is when the parietal layer has become adherent to the visceral layer when the heart was already dilated at the time of the pericarditis that symptoms subsequently accrue, the result rather of the inability of the already big heart to maintain sufficient hypertrophy than of any intrinsic interference with its action by the adherent pericardium itself. Fatal mechanical failure of the heart before puberty in a patient who presents no symptoms of rheumatic reinfection points to adherent pericardium.

Adhesions between the parietal pericardium and the structures outside it, without any adhesion between the parietal and visceral layers within the pericardium, are exceedingly common, generally resulting from former pleurisy. The former inflammation must have extended outside both the pericardium and the pleuræ, so that it was really a mediastinitis : but clinically the condition is seldom spoken of as mediastinitis, because it is of very little importance, and in itself produces no symptoms ; the physical sign which might suggest it is deficiency in the movement of the position of the cardiac impulse to the left or to the right as the patient rolls from one side to the other ; the condition is very likely the cause of some of the queer little bruits that are so often met with in patients who have no disability and yet who are apt to have their lives spoiled by their being diagnosed as valvular disease cases merely because there is a bruit. It is only experience that can help one in deciding that such bruits are exocardial and unimportant : the tendency should be rather to exclude than to diagnose organic valvular heart disease if there are no symptoms, and if the site, direction of transmission, and general character of the bruit do not compel one to the more serious alternative.

The third variety of adherent pericardium—namely, that in which there are adhesions

between the parietal and visceral layers and between the parietal layer and the chest wall, pleura, and other structures outside it—is really a combined condition of adherent pericardium and mediastinal adhesions which, when an extreme degree is reached, becomes what is known as chronic mediastinitis. Here again, it is possible for neither symptoms nor physical signs to present themselves, the condition being found unexpectedly in the post-mortem room; but on the other hand it may be the cause of grave cardiac disability, and it is this condition which is generally diagnosed under the name of adherent pericardium. There may be a history of former pericarditis, pleurisy, or both, probably rheumatic. The heart will be large out of all proportion to any valvular disease that is present, without there being other obvious cause for its hypertrophy and dilatation, such as nephritis, arteriosclerosis, hard work, alcoholism, fatty or fibroid heart, or chronic lung disease. If the parietal pericardium is adherent both to the pleura and to the diaphragm—particularly the latter—there will very likely be retraction of the lower left ribs posteriorly, synchronous with the heart-beat, known as Broadbent's sign; this is generally regarded as pathognomonic of adherent pericardium, and it certainly is very suggestive of this lesion; but it may be present with hypertrophied hearts to which the pericardium is not adherent. It needs to be looked for with some care; the observer watches the posterior profile of the left chest; small movements obviously due to cardiac and not respiratory action are to be seen in the ninth, tenth, or eleventh intercostal space in the line of the scapula, or just outside this; irregularity in the heart's action often renders these visible only now and then—perhaps only when a strong heart-beat happens to coincide with the most favourable phase of respiration. Another physical sign which is regarded by some as indicative of general pericardial adhesions is an ingoing impulse in the third or fourth intercostal space between the left nipple and the left border of the sternum, synchronous with an outgoing impulse nearer the apex, giving an oscillating or see-saw appearance to the precordial region—some of the intercostal spaces moving inwards at the same time as others move out with the heart-beat. The probable cause of the ingoing movement nearer the sternum when the part of the heart which is nearer the apex causes the ordinary outgoing impulse, is the visible withdrawal of the hypertrophied right ventricle as it contracts; so that this see-saw appearance in the precordial region is indicative merely of great hypertrophy of the right ventricle without proving decisively what is the cause of this hypertrophy. Amongst these causes is adherent pericardium; but a similar appearance is often seen in cases of extreme mitral stenosis of long standing, even when there is no adherent pericardium, and it may result from any cause of cardiac hypertrophy in which the right heart takes part.

6. Bright's Disease may produce ascites in more ways than one; the effusion may, for instance, simply be part of a general anasarca, the accumulation of the ascitic fluid in the peritoneal cavity corresponding precisely with its accumulation in the subcutaneous tissues; or the Bright's disease may lead to acute or chronic peritonitis of the types described above; or, especially in chronic cases associated with pale or red granular contracted kidneys, there may be failure of the dilated and hypertrophied heart, with ascites, which may be very difficult to distinguish from that of primary heart disease; especially as the greater part of the associated albuminuria is now the result of the heart failure rather than of the renal sclerosis, and casts may seem unduly few in proportion to the albumin. If the blood-pressure is very high the diagnosis is more likely to be arteriosclerosis or granular kidney than primary heart failure, though, curiously enough, the blood-pressure is generally above normal in heart failure from any cause, even when the pulse is as irregular and feeble as it often is in the late stages of mitral stenosis. This terminal rise of blood-pressure in heart cases probably results from the partial asphyxia.

7. Severe Anæmias often cause ascites, but they do not give rise to much difficulty in diagnosis, because the subacute or chronic peritonitis which is the cause of the ascitic exudate in these cases arises, as a rule, comparatively late in the disease, after the diagnosis has been made on other grounds, by blood-counts and otherwise. (See ANÆMIA, p. 25; SPLEEN, ENLARGEMENT OF, p. 774; LYMPHATIC GLAND ENLARGEMENT, p. 471.) One need not do more here than refer to the huge enlargement of the spleen without lymphatic glandular enlargement, and the great leucocytosis with a large proportion of myelocytes, in *splénomedullary leukaemia*; the considerable leucocytosis, the enlargement of the lymphatic glands and probably of the spleen, and the great relative increase of the small lymphocytes,

in *lymphatic leukaemia* : the enlargement of the lymphatic glands and of the spleen, and the absence of any positive blood changes, beyond anaemia of the chlorotic type without leucocytosis, in *Hodgkin's disease* : the enlargement of the spleen, the absence of lymphatic glandular enlargement, and the occurrence of a progressive and ultimately severe anaemia, of the simple chlorotic type without leucocytosis, but with an occasional myelocyte and basophil corpuscle, in *splenic anaemia* when it has reached the stage of cirrhosis of the liver - Banti's disease ; the profound anaemia and the high colour-index without leucocytosis, in *pernicious anaemia* ; the severe anaemia suggestive of pernicious anaemia, but with a persistently low colour-index, in *aplastic anaemia* ; and the splenic enlargement with profound chlorotic anaemia without leucocytosis, in *pseudoleukemia infantum*. The differential diagnosis of *familial splenomegaly*, *acholuric jaundice*, *Egyptian splenomegaly*, and *kala-azar* is discussed elsewhere ; in all of them ascites is a late or terminal phenomenon, the diagnosis depending upon earlier symptoms, especially the enlargement of the spleen.

8. **Chylous Ascites** is not in itself a specific malady, for there is more than one condition in which the ascitic fluid may appear like milk. This may result from obstruction to the main abdominal lymphatics, particularly the receptaculum chyli and thoracic duct : or from their rupture after injury to the abdomen : more often the condition is associated in this country, in some way which is not fully understood, with the peritonitis of chronic *Bright's disease*, or of *leukaemia*. The best-known tropical cause for chylous ascites is *Filaria sanguinis hominis* with elephantiasis. In rare cases the secondary deposits of malignant disease may be such as to obstruct the thoracic duct and so produce the chylous condition of the ascitic fluid. Chyluria may or may not occur at the same time. The chylous ascites of chronic tubal nephritis may be associated with *lipaemia* precisely similar to the lipaemia of diabetes mellitus : curiously enough, lipaemia may be present in chronic tubal nephritis without its being suspected at all : the condition of the blood being discovered accidentally sometimes, for instance, when a specimen has been taken for testing the Wassermann reaction (*Fig.* 273, p. 334) : such lipaemia may be present without any ascites at all, or the ascites that may be present may be clear even when there is lipaemia.

There are two types of chylous ascites, one in which actual chyle accumulates in the peritoneal cavity as the result of direct leakage from the thoracic duct or receptaculum - true chylous ascites : the other in which the condition is in the main one of ascites, but the fluid becomes milky-looking from little-understood chemical changes taking place in it, particularly in the proteins. This is termed chyliform ascites, or pseudochylous ascites. There is much more real fat in the former condition than in the latter : but chyliform ascites is commoner than true chylous ascites. The diagnosis between the two is afforded by chemical and microscopical analyses of the fluid obtained by tapping, the chief points of distinction being as follows :—

Chylous Ascites.

1. The fluid tends to accumulate very rapidly, and in consequence large volumes are removed at paracentesis.

2. Generally yellowish-white in colour and less perfectly emulsified.

3. Degree of opalescence more or less constant at successive tapplings.

4. Possesses an odour corresponding to the odour of the food ingested.

5. Microscopically the fluid contains fine fat globules, but very few cellular elements.

6. Generally shows a distinct creamy layer on standing.

7. Specific gravity generally exceeds 1012.

8. Depression of freezing point about 0.51°C . and approximating that for chyle.

Chyliform Ascites.

1. Collects more slowly, the volume of the fluid varying with the exciting pathological condition.

2. In colour a pure milky-white solution in the form of an almost perfect emulsion.

3. The opalescence generally increases or diminishes at successive tapplings.

4. Odourless.

5. Microscopically the quantity of free fat is variable : often numerous fine, highly refractile granules are present, and these do not give the reactions for fat. Cellular elements may be numerous and often contain fat : sometimes very scanty.

6. A cream may or may not form, but it does not affect the opalescence ; a sediment frequently settles out.

7. Specific gravity less than 1012.

8. Depression of freezing point ranges from 0.56° to 0.61° , and thus corresponds to the figures for blood serum.

Chylous Ascites.

9. Total solids vary considerably, but usually exceed 4 per cent.

10. The total protein content generally exceeds 3 gm. per cent, and of this the serum-albumin is the largest fraction, globulin occurring only in traces.

11. Mucinoid substances absent.

12. The fat content is generally high, varying from 0.4 to 4 per cent. The fat corresponds in all its properties to the fat contained in the food that is being taken.

13. Of the lipins, cholesterol is invariably found, and lecithin only occurs in traces.

14. There is no evidence of the presence of a lipin-globulin combination.

15. The salts and the organic substances present approximate to the values found for chyle obtained from the thoracic duct.

Chyliform Ascites.

9. Total solids rarely exceed 2 per cent.

10. The protein constituents vary between 1 and 3 gm. per cent, and of these the serum-globulin occurs in appreciable quantities.

11. Mucinoid substances present.

12. The fat content is generally low, and it may be present in traces only; in its melting and chemical composition it does not vary *pari passu* with variations in the kinds of fat that are being eaten by the patient.

13. The most characteristic lipin is lecithin, though cholesterol is occasionally present.

14. The lecithin is mainly combined with the globulin, and this combination is usually the cause of the opalescence of the fluid. Such fluids resist putrefaction.

15. The salts and organic materials correspond closely to those of lymph and serous fluids.

9. Semi-starvation as a cause of ascites is generally diagnosed from concomitant circumstances. It was common in Europe during the great war. When people have been compelled by famine to subsist for long periods upon dietary inadequate in variety as well as in amount various illnesses of malnutrition may result. The total calories in the food eaten may suffice to maintain a bare existence, but disease ensues. Beri-beri, often with oedema of the legs, is a familiar result of long-continued eating of decorticated rice as the main staple of diet; general oedema of the whole body, simulating Bright's disease, was often met with in Germany and Russia from famine dietary in the war; and a certain number of people suffering from anasarca from this cause exhibited ascites as part of their general oedema.

Herbert French.

ATAXY is the term used to describe voluntary movements which are imperfectly controlled or co-ordinated. It is displayed in its simplest form by infants under the age of one year. In pathological states it is often a symptom of great diagnostic importance; but before its value as a localizing sign of disease can be utilized it is necessary to appreciate broadly the physiological mechanism by which co-ordination is brought about, and the possible situations of a lesion able to disturb the smooth working of that mechanism. For the proper co-ordination of voluntary movement, impulses from the muscles, tendons, joints, and skin of the part which is moved must reach the brain. These impulses are of two kinds:—

1. Sensory afferent impulses which are carried to the *cerebrum* by way of the peripheral nerves, Goll's and Burdach's posterior columns of the cord, the gracile and cuneate nuclei in the medulla oblongata, the fillet, and finally from the basal ganglia to the cortex in the neighbourhood of the motor area. These impulses cross from one side of the body to the opposite hemisphere, the crossing taking place in the medulla.

2. Non-sensory afferent impulses, so-called because they never reach consciousness, pass from the peripheral structures concerned in movement, by way of the peripheral nerves and the ascending cerebellar tracts of the cord, to the *cerebellum*, and principally to the cerebellar lobe of the same side of the body. In some manner which is not perfectly understood, but in which preservation of muscular tone is probably concerned, the co-operation of the cerebellum is required if movements initiated in the motor area of the cerebrum are to be carried out in a co-ordinate manner.

Not only must these two sets of impulses reach the brain, but the parts of the brain, cerebral and cerebellar, which form their destination must also be intact if voluntary movement is to be carried out with accuracy and co-ordination.

From the clinical point of view it is necessary to ascertain in the first place whether a patient is ataxic, and in the second whether the ataxy can be attributed to the loss of the sensory or non-sensory afferent impulses. In some cases the ataxy is obvious; in others it can be detected only by the careful application of certain tests. For instance, a patient may walk into a well-lighted room with perfect ease and without anything remarkable in his gait, but if he is asked to walk along a line, placing one foot exactly in front of another,

he may at once display his lack of co-ordination. Such ataxy may be just as important from a diagnostic standpoint as the imperfect attempts of an advanced tabetic patient to walk even when supported by companions on either side. It is the quality and not the quantity of a defect which gives the needed information.

The co-ordination of movements performed by the upper extremities must also be investigated with the same care. The patient may handle his stick in quite a natural manner, but if asked to unbutton and button his coat, to touch the tip of his nose with the tip of his finger, to write, etc., he may fail to convince the observer that his control of fine movements is up to the normal standard.

Having ascertained the existence of ataxy, the next step is to decide whether it is dependent on the loss of sensory or non-sensory afferent impulses, or on the imperfect function of the cerebrum or cerebellum. If the ataxy is due to loss of sensory impulses it will be increased by the loss of visual impulses brought about by closing the eyes—Romberg's sign. It will also be possible to demonstrate the loss of sensory impulses by asking the patient to describe the position of a limb with his eyes closed after it has been moved by the observer. When these two tests are positive, it may be assumed safely that the lesion affects the first set of impulses or their cerebral destination.

If, on the other hand, the ataxy is uninfluenced by closing the eyes and the patient is perfectly accurate in describing the position of his limbs, it is probable that the cerebellar tracts are at fault, or the cerebellum itself.

For further localization of the lesion in any particular case it will be necessary to take into account concomitant phenomena.

Interference with the passage of impulses necessary for proper co-ordination may be provoked by lesions in (1) *The peripheral nerves*; (2) *The spinal cord*; (3) *The brain-stem*; (4) *The cerebrum*; and (5) *The cerebellum*. Let us now consider the effect of lesions in these different regions, and the diagnostic evidence as to their localization afforded by ataxy.

1. Peripheral Nerves.—A severe lesion of a peripheral nerve must lead to ataxy of movements performed by the muscles to which it is distributed: a severe lesion will also paralyse the muscles, however, and thus prevent any ataxy being demonstrated. Less severe lesions, such as occur in slight cases of peripheral neuritis, allow of some voluntary movement, so that ataxy becomes demonstrable. Thus a case of peripheral neuritis of alcoholic or diphtheritic origin may show impaired strength, together with ataxy in all four limbs. The diagnosis of a peripheral nerve affection in such a case will depend on the following points:

In the first place, the symptoms will be found to be symmetrical, and in the affected limbs the impairment of strength will be most marked in the extensors of the wrists and ankles.

Secondly, slight anæsthesia to cotton-wool may be detected over the glove and stocking areas. With regard to pain, there may be blunted cutaneous sensibility to the prick of a pin over the same area, but almost constantly deep pressure on the affected muscles will establish the fact that these tissues are abnormally sensitive. This is a most important point in diagnosis, because it strikes an essential distinction between cases of ataxic peripheral neuritis, sometimes described as pseudo-tabes, and cases of true spinal tabes, in which it is an almost invariable rule to find diminution or loss of painful sensibility on squeezing the muscles—analgesia.

In the third place, the tendon reflexes will be markedly diminished or completely absent, while the plantar reflexes will probably be unobtainable.

Fourthly, the use of electrical currents upon the muscles will show that the response to faradic currents is materially lessened or abolished, and that the contraction excited by the make and break of the galvanic current may be of the slow, worm-like type so characteristic of the reaction of degeneration (p. 724).

The ataxy of peripheral neuritis has in itself no reliable characteristic to distinguish it from ataxy due to spinal disease. That it is due to a lesion of the peripheral nerves is concluded, not from the nature of the ataxy, but from the presence of other symptoms also referable to interference with the functions of the nerves. The gait is unsteady, and the patient keeps his legs apart in order to lessen the tendency to lose his balance. The clumsiness of the upper extremities may be demonstrated by his inability to bring the first finger of one hand accurately into apposition with that of the other, or to touch

the tip of his nose with either. Both the unsteadiness of gait and the awkwardness of the fingers are exaggerated if he attempts to walk, or carry out movements with his hands when his eyes are closed. A tendency to high-steppage will be noticeable in walking if, in addition to the ataxy, there is well-marked paresis of the dorsiflexors of the ankles. In such a case the patient is obliged to lift the feet to an unusual height in order to clear the ground, and the fact may be noticed first from the way in which he wears through the toe end of his boot-soles with a rapidity that was not formerly the case.

2. Spinal Cord. The ataxy due to disease of the spinal cord is seen best in *tubes dorsalis*, in which malady degeneration of the posterior column ascending tracts occurs early, and in which, consequently, the patient does not receive the normal impulses from the muscles, tendons, and joints so necessary for the preservation of his sense of position and movement. Contrary to popular ideas, gross ataxy is met with only in a small proportion of the cases of this disease, and it is often necessary to apply delicate tests to demonstrate its presence. The patient's gait may not be remarkable in good daylight, but he may complain of its uncertainty in the dark, or he may be obviously ataxic with his eyes closed. Another patient may have noticed nothing amiss with his walking in the ordinary way, but if he is asked to follow a line on the floor, placing one foot exactly in front of the other, his impaired power of balance will become apparent, especially if he is directed to accomplish this test with his head raised and his eyes fixed on something in front of him instead of upon his feet.

In cases of moderate tabetic ataxy the gait and stance of the patient are remarkable for the wide base he assumes, and his tendency to guide his feet by means of his vision. Romberg's sign can be obtained easily. This sign is not diagnostic of *tubes*, as is so often assumed, but is merely used for the purpose of ascertaining whether the removal of visual impulses will convert a condition of stability into one of instability. Many, if asked to describe Romberg's sign, reply, "You direct the patient to put his feet together and close his eyes: if he sways or falls, the sign is present." This is obviously incorrect, because the patient may sway even before his eyes are closed. In order to test a patient for this sign he must be directed to stand with his feet as near together as he is able to do with steadiness, and, having established his stability in that position with open eyes, he must be told to close the latter. If he then sways or tends to fall, it is clear that he had been depending on his visual impulses, and that, without their aid, the impulses derived from his legs and trunk were insufficient for the preservation of his equilibrium. We have in this test, therefore, a valuable method of ascertaining whether the function of the posterior columns is being carried out normally.

To judge from the descriptions given in some text-books, the typical gait of *tubes* is one in which the legs are thrown into the air and the feet brought to the ground with a more or less noisy stamp. As a matter of fact, this type of gait is seen only in a small proportion of cases, and is rarely observed except when the patient is depending for support either on a couple of sticks or on one or two attendants. In other words, he has become so ataxic that he cannot walk unsupported, and, being supported, he no longer attempts to control the exuberance of his leg movements by means of his sight.

Tabetic ataxia in its moderate and extreme degrees can be demonstrated when the patient is at rest in bed, by asking him to carry out accurate movements with his hands and feet, with and without the aid of his vision. In slighter degrees the fact that the ataxia is dependent on interference with his sense of position and movement may be proved by asking him to describe the position of a finger or toe which the observer moves in different directions whilst the patient is prevented from seeing it. Sometimes it is as well in testing this sense in one limb to ask the patient to place the corresponding limb in the same position, when the error will be made more obvious.

The diagnosis of *tubes* cannot be made from the character of the ataxy alone, since in other diseases, such as Friedreich's ataxy, disseminated sclerosis, or combined degeneration of the cord, there is or may be sclerosis of the posterior columns resulting in similar inco-ordination. It is important, therefore, to remember that in *tubes* the posterior roots are affected also, and that there is very often some interference with other afferent impulses, especially those which convey sensations of pain from the muscles and skin, and those which are concerned with the deep reflexes and the maintenance of muscular tone. Thus, in this disease one of the earliest symptoms is relative analgesia to pin-pricks and to deep

pressure on the muscles in the lower extremities ; at the same time it must not be forgotten that the tabetic phenomena may be limited to the upper extremities (cervical tabes).

In *Friedreich's ataxy*, *disseminated sclerosis*, and other spinal disease, as well as in some cases of tabes, the ataxy due to the lesion of the posterior columns may be complicated and intensified by the fact that there is also interference in the path of the non-sensory afferent impulses, which pass from the extremities to the cerebellum via the ascending cerebellar tracts in the spinal cord. If this form of ataxy is present, the help which the patient derives from vision for the purpose of controlling his inco-ordinate movements is largely discounted, and he may be as ataxic with open as with closed eyes.

In some lesions, such as those resulting from *syringomyelia* or *new growth* of the spinal cord, only one side of the cord may be affected, and a Brown-Séquard form of paralysis be exhibited (p. 608). If the paralysis is not complete, some ataxy may be observed in the paretic limb.

3. The Brain-stem.—Lesions of the medulla, pons, or crura cerebri may produce ataxy if they interfere with the passage of either sensory afferent impulses to the cerebrum or non-sensory afferent impulses to the cerebellum. The cerebellar impulses can be interfered with only at the medullary level ; that is to say, before they have passed into the cerebellum via the inferior peduncle. A good example of hemiataxia of this origin is afforded by any case of *thrombosis of one posterior inferior cerebellar artery*. This uncommon condition affects the structures on one side of the medulla, and is characterized by hemiataxia of the homolateral limbs, together with loss of sensibility to pain, heat, and cold on the contralateral side. The ataxy is of the cerebellar type ; that is to say, it is not associated with loss of sense of position and movement in the affected limbs, and is little influenced by closure of the eyes. Above the medulla, lesions which are capable of producing ataxy by interfering with the sensory impulses from the muscles, joints, and tendons usually cause paralysis of the same parts, so that the co-ordination is more latent than real, and therefore of little diagnostic importance.

4. The Cerebrum. From the basal ganglia to the cortex the path of the afferent impulses necessary for co-ordinate movements lies near to that of the efferent impulses from the motor area, and it is only rarely that lesions affect the sensory fibres and leave the motor intact. Every now and then, however, a patient complaining of loss of use of the limbs on one side is found to be suffering from impaired sense of position and movement in those limbs rather than from paralysis. His co-ordination may be fairly good so long as he can utilize his vision, but with closed eyes he has no notion of the position of his arm or leg, and no knowledge of the nature of objects placed in his hand (*astereognosis*). This may even be the case when other sensory stimuli, such as those of touch, pain, and heat, are appreciated perfectly. A similar condition may be observed during recovery from a slight hemiplegic 'stroke', the patient displaying a degree of clumsiness and awkwardness with his fingers quite out of proportion to his loss of voluntary power. A process of education for finer movements, similar to the education of early life, is necessary before he is able to overcome this form of ataxy.

Ataxic movements are not uncommon in the subjects of *infantile hemiplegia*. The hand on the affected side may be permanently clumsy and incapable of carrying out the delicate manipulations necessary for writing, sewing, etc. In other cases all voluntary efforts are interfered with by the constant presence of involuntary movements of an athetotic, choreiform, or tremulous character, sufficient to prevent their attaining any dexterity.

Whatever the nature of the lesion, cerebral ataxy is generally characterized by its hemiplegic distribution, and by its increase when the eyes are closed ; generally the loss of impulses subserving the sense of position and movement, and often of other sensory impulses, can be demonstrated by suitable tests.

5. The Cerebellum.—Cerebellar ataxy may be unilateral, as in some cases of *tumour* of one lateral lobe, or bilateral, as in the *acute cerebellar ataxia* of children due to encephalitis. In unilateral cases the ataxy is most marked on the same side as the lesion, and is associated with hypotonia and some paresis of the affected limbs. On the other hand it is important to note that the reflexes on the affected side are normal, that the ataxy is not accompanied by any loss of sense of position and movement, and that closure of the eyes does not materially increase the patient's disability. The ataxy often differs from that due to disease of the posterior spinal column in that it is complicated by vertigo. This may take

the form of a sensation of rotation on the part of the patient, or of rotation of surrounding objects, sometimes of both. The vertigo and the ataxy are generally much less noticeable in the recumbent position. The cerebellar gait resembles that of a drunken man; the patient reels from side to side, with a general tendency to deviate or fall to the side of the lesion if only one lobe is affected. He is unable to balance himself properly on the homolateral foot, and his manual dexterity is impaired, so that he may be unable to feed or clothe himself. The ataxia is not always limited to the trunk and limbs, but may affect the tongue, lips, palate, and vocal cords, so that their movements may be controlled imperfectly, and a characteristic 'cerebellar articulation' attracts attention. Finally, a lesion of the cerebellum sufficient to cause ataxy nearly always causes nystagmus also, which, in disease of one lobe, is more marked during deviation of the eyes to that side.

Hysterical Ataxy. Ataxy is sometimes hysterical, and may then be the only disorder of function exhibited by the patient, or may be associated with hysterical hemiplegia, paraplegia, hemianesthesia, etc. The diagnosis depends partly upon the absence of signs of organic disease, partly on the presence of other hysterical stigmata, and partly on its character. For example, we may cite the case of a boy who, when lying in bed, was able to feed himself and to carry out all movements of his upper and lower limbs with perfect accuracy, but who, when placed on his feet and told to walk, displayed the wildest inco-ordination and loss of equilibrium. It was noticeable, however, that he always reached some chair or bed on which to collapse finally, even when placed in the middle of the room at some distance from any support. It would, of course, be unjustifiable to apply this last test before the observer was satisfied from careful examination that there were no signs of organic disease.

Traumatic Ataxy. The protean characters of nervous disabilities resulting from injury were seen in innumerable cases during the war. Many of these were due to the effects of sheer fright—emotional shock; some to the results of disseminated organic changes in the cord or brain from real injury or petechial hemorrhages resulting from the injury—commotional shock or true shell-shock. Ataxy was a frequent concomitant of either, and sometimes it persisted. Similar ataxy from emotional or commotional changes results, in civil life, from the effects of railway accidents, motor-car smashes, and so forth. An allied state of affairs may be seen sometimes in divers, caisson workers, balloonists, and even aeroplane pilots, as the result of rapid changes in the atmospheric pressure to which the body as a whole is subjected: small bubbles of oxygen may be liberated in the tissues of the central nervous system as the result of too rapid decompression, and it is these apparently that cause the damage. In many traumatic cases the diagnosis is clear enough, but it may be difficult to assess how much of the trouble is the result of the emotional (functional) factor, and how much the commotional (organic). A careful history and the experience of the examiner go far in deciding.

Ataxy due to Mental Shock or Fright. The emotional factor in connection with 'railway spine' and emotional shell-shock has just been discussed; but there are other cases of purely emotional ataxy in which there has been no traumatic factor. One speaks of 'staggering news', of having a 'staggering blow' on the exchange, and so on. Any extreme emotion, pleasant or unpleasant, may cause temporary ataxy; the worse the emotion the longer the ataxy is apt to last; and after extreme fright, panic, or the like, it may be permanent though functional.

Ataxy due to Chemicals and Drugs. Alcohol is probably the most familiar of chemical substances causing ataxy and staggering gait; the difficulty of deciding whether, after a motor smash, the consequent ataxy is the result of drink or of the accident is becoming a real problem in the law courts. Many other chemicals or drugs may produce transient ataxy; one need not give a complete list, but one may mention the hypnotics in particular. An overdose of veronal may be followed by staggering gait for weeks. Certain chemicals may cause slow progressive organic changes in the central nervous system associated with ataxy, such as may be seen sometimes in manganese workers, and less frequently in aluminium workers. The effects of certain fumes include ataxy, notably the products of incomplete combustion of coal-gas, coke, and petrol. These sources of obscure ataxic symptoms may not be diagnosed unless they are borne in mind or inquired about.

Ataxy due to Senility, or the Effects of Systemic Illness—convalescence ataxy—is generally attributable to its cause without any difficulty.

E. Farquhar Buzzard.

ATHETOSIS.—(See CONTRACTIONS, p. 168.)

ATROPHY, MUSCULAR.—Muscular atrophy is often merely part of a *general wasting of the whole body*, due either to chronic lesions such as carcinoma, sarcoma, tuberculosis, syphilis, malaria, ulcerative colitis, marasmus, starvation, hepatic abscess, cirrhosis

Fig. 79.—Hand from a case of pseudo hypertrophic muscular paralysis, showing the marked wasting of the abductor indicis.

of the liver, diabetes mellitus, anorexia nervosa, or to acuter maladies, such as diarrhoea and vomiting, ptomaine poisoning, typhoid fever, dysentery, cholera, and so forth. The history, and the other symptoms in the case, will usually serve to indicate these. If any doubt remains as to whether the atrophy is neurotrophic or not, the electrical reactions will be tested; there will be no reaction of degeneration (R.D.) when the atrophy is merely part of a general wasting, whereas if as might be the case in a diabetic patient, for instance there is peripheral neuritis in addition, this will be indicated by a partial or a complete R.D. (See REACTION OF DEGENERATION, p. 724.)

In the next place, the atrophy may be the result of *disuse*. Organic disease of the nervous system may or may not be present at the same time; the patient may be bedridden from locomotor ataxy, for example, or from general paralysis of the insane; and the muscles of the limbs may consequently become so thin that peripheral neuritis or degeneration of the anterior cornual cells may be simulated, and a determination of the absence of R.D. may be

the only means of excluding these. It is important to remember that in the *primary muscular dystrophies*, whether of the pseudo-hypertrophic (Fig. 79), the juvenile, the infantile, the facio-scapulo-humeral or Landouzy-Dejerine, or other types, there is no reaction of degeneration, the electrical responses and the superficial and deep reflexes remaining normal in type, though they diminish in degree as the amount of muscle grows less and less, until finally there is no muscle to respond at all. The primary muscular dystrophies (p. 624) are comparatively easy to diagnose, however, on account of their insidious onset generally in childhood or in early life, their

but progressive downhill course, their occurrence in different members of the same family, the absence of sensory disorder, and the absence of R.D. They are distinguished from *infantile paralysis* which results from acute anterior poliomyelitis (Fig. 80) by the latter having a sudden onset, R.D. at its height, whilst the resultant wasting does not advance progressively, but, after recovering to a certain degree, tends to remain stationary.

Peripheral neuritis is distinguished from primary muscular dystrophy by the history and course, and by the presence of R.D. at some period of the malady. Two other affections that may be confused with a primary muscular dystrophy—particularly as they also are hereditary, begin insidiously at an early age, and slowly advance—are *Friedreich's ataxy*, and *Tooth's peroneal type of progressive muscular atrophy*. Each of these may cause talipes, moreover, and therefore simulate infantile paralysis, except that in the latter the

Fig. 80. Atrophy of the muscles of the left shoulder and upper arm, the result of former acute anterior poliomyelitis—infantile paralysis.

talipes is generally one-sided, whereas in the other two it is bilateral. In Friedreich's ataxy (see p. 624) there is no real wasting, but rather a lack of development. Tooth's peroneal type of progressive muscular atrophy is apt to come on after some febrile malady such as measles or whooping-cough, the first thing noted being inability to dorsiflex the big toe, which hangs down (*Fig. 81*) in a way that is the exact converse of its erect position in Friedreich's ataxy; the paresis takes months or years to spread to the rest of the legs, and finally to the hands (*Fig. 82*), the slowness of the progress and the absence of sensory symptoms showing that it is not peripheral neuritis, whilst the R.D. in the affected muscles excludes a primary muscular dystrophy. The lesion is in the anterior cornual cells, and starts in the lumbar enlargement. The knee-jerks are retained until the quadriceps of the thigh is involved.

Local muscular atrophy may be due to *disease of the parts beneath*, as in the case of the pectoralis major, the supraspinatus, the deltoid, the infraspinatus, and other shoulder

Fig. 81. Tooth's peroneal type of neuro-muscular dystrophy early; the patient is the younger brother of the girl in *Fig. 82*. Note the plantar flexion of the big toe and the drooping of the feet; the calves are not yet wasted.

Fig. 82. Tooth's peroneal type of neuro-muscular dystrophy; the patient is sister to the boy in *Fig. 81*; her malady is in a much more advanced stage than is his, wasting having extended to the calves, thighs, hands, and forearms.

Fig. 83. Hemiatrophy of the tongue in a case of syringomyelia. (Lent by Dr. Copey Coombs.)

muscles when the underlying lung is the site of active phthisis.

Similar local atrophy results very quickly from acute and subacute affections of joints, especially in the muscles whose origin is above the affected joint. The gluteal atrophy associated with tuberculous hip-joint is well known; similarly, knee-joint disease leads to thigh atrophy, elbow disease to atrophy of the muscles of the upper arm, and so on. The same applies to the effects of fractures, new growths, sprains, and splints; the atrophy is sometimes so rapid that some think it cannot be due simply to disuse, but must have a neuropathic factor also. The affected muscles present no R.D., however. One particular form of paralysis associated with the use of splints merits special mention, namely, Volkmann's paralysis of the forearm. (See PARALYSIS OF ONE UPPER EXTREMITY, p. 617.)

Hemiatrophy of the face or trunk is generally congenital, and the diagnosis is not difficult (see *Fig. 468*, p. 605).

If it is possible to come to a definite conclusion that there is some nervous cause for muscular atrophy, the best proof of which is the detection of partial or

complete R.D., the diagnosis lies between one or other of the following conditions:—

1. Causes in the Spinal Cord.—

Progressive muscular atrophy
Amyotrophic lateral sclerosis
A few cases of transverse
myelitis

Syringomyelia (see *Fig. 83*)
Tooth's peroneal type of pro-
gressive muscular atrophy
Acute anterior poliomyelitis

Tumour of the cord, or of its
meninges, destroying the
underlying anterior cornual
cells

2. Causes in the Peripheral Nerves.—

Tumours of the cauda equina
Pelvic tumours involving the
lumbo-sacral plexus
Sciatica
Aneurysm

New growth
Accessory cervical rib, etc.,
pressing on the brachial
plexus

Gummata, etc., involving the
cranial or other nerves
Injury to peripheral nerves,
including the effects of callus
after fractures

Peripheral neuritis, of which the following are some of the causes :

Certain inorganic chemical
substances, notably :

Lead
Arsenic
Mercury

Certain severe anemias :

Pernicious anaemia
Splenomedullary leukaemia
Lymphatic leukaemia
Hodgkin's disease
Splenic anaemia

Beri-beri
Syphilis
Typhoid fever
Influenza
Oral sepsis

Certain organic chemical com-
pounds, notably :

Alcohol
Ether
Carbon bisulphide
Naphtha

Certain microbial or allied
toxins :

Diphtheria
Leprosy
Malaria
Chronic pyaemia
Infective endocarditis

Certain constitutional diseases
associated with endo-
genous poisons :

Gout
Diabetes mellitus

Pregnancy

Other causes as yet undeter-
mined

In arriving at a diagnosis in a particular case it is important not to use the term 'neuritis' until all the other possible lesions have been excluded. Tooth's peroneal type of progressive muscular atrophy and acute anterior poliomyelitis have already been discussed. The latter is sometimes regarded as essentially a disease of early life, but it often affects an adult, in whom the symptoms and results may be precisely similar to what they would be in a child.

Progressive muscular atrophy is a disease of adults. It shows no particular tendency to occur in several members of the same family. It begins insidiously, and advances slowly for months and years, affecting firstly the small muscles of the hands, causing atrophy with R.D. in the interossei (*Fig. 84*) and the muscles of the thenar and hypothenar eminences : the peculiar deformity described as 'main-en-griffe' results (p. 144). In the course of months the paresis spreads from the hands to the forearm, and later to the upper arm. Disease of the peripheral nerves, such as the ulnar, is excluded by the fact that the paralysed muscles are not all supplied from the same nerve-trunk—the thenar muscles supplied by the median being affected equally with the hypothenar supplied by the ulnar. All the muscles below the wrist are involved more or less together, then all the muscles below the elbow, and so on up the arm : this paralysis of associated groups of muscles as distinct from muscles supplied by the same nerve at once suggests a progressive degeneration of the anterior cornual cells of the cervical enlargement of the cord. Disease of the brachial plexus would be excluded first by the fact that the lesion is bilateral and symmetrical, and secondly by the absence of pain or other sensory disturbance. The pathology of the disease is analogous

Fig. 84. The dorsum of the left hand, showing atrophy of all the interossei muscles, in a case of early progressive muscular atrophy. The wasting of the abductor indicis is particularly marked. The ring and little fingers are beginning to become contracted into the 'main-en-griffe' attitude.

to the nuclear cell-degeneration in the medulla oblongata that leads to bulbar (labio-glosso-pharyngo-laryngeal) paralysis : and indeed, progressive muscular atrophy may either follow or be followed by bulbar paralysis.

If at the same time that there are the signs of progressive muscular atrophy in the hands there is also spastic paresis of the legs, with no wasting, but increased knee-jerks, ankle-clonus, and extensor plantar reflexes, the onset having been quite gradual, without

sensory disorder, and without bladder or rectal trouble unless the disease has reached quite a late stage, the condition is *amyotrophic lateral sclerosis*.

It is important that the character of the onset and the absence of sensory symptoms be insisted on, in order to exclude syringomyelia and anomalous cases of transverse myelitis. *Syringomyelia* is rare, but it has one very characteristic feature, namely, the preservation of ordinary cutaneous sensibility with the loss of power of distinguishing heat from cold, or pain from touch, in some part of the limbs or trunk. There need be no other symptom than this dissociation of sensations, and attention may be drawn to it first by the development of skin lesions in the paræsthetic parts owing to the effects of burns or cuts or other injuries which the patient has not felt at the time because of his inability to experience pain or to distinguish heat in the affected parts—*Morvan's disease*; if the hypergliomatosis in and around the central canal of the cord, which is the essential pathology of the disease, displaces and destroys the anterior cornual cells in the lower part of the cervical enlargement, progressive muscular atrophy is simulated; if at the same time the bulging of the central canal and the changes around it cause compression of the crossed pyramidal tracts, there will be all the motor symptoms and signs of amyotrophic lateral sclerosis, the diagnosis being only possible when the sensory symptoms are typical.

It is generally stated that *transverse myelitis* causes spastic paraplegia without muscular wasting or R.D. This is in the main true, because the few anterior cornual cells destroyed by the transverse softening of the cord in the commonest site, namely the dorsal region, correspond to an intercostal or abdominal segment, the wasting of which is difficult to detect. If, however, the transverse myelitis occurs so high up as to involve the lower part of the cervical enlargement—to involve the cord yet higher up is incompatible with life, because both the intercostals and the phrenic nerves would be paralysed—a certain number of the anterior cornual cells sending motor nerves to the hands and arms would be destroyed, the result being a main-en-griffe like that of progressive muscular atrophy; and the simultaneous interference with the crossed pyramidal tracts would produce a picture identical at first sight with amyotrophic lateral sclerosis. In a case of transverse myelitis, however, there would probably be impairment of all forms of sensation as well as paresis, and instead of the onset being gradual and the progress a steady advance downhill, as in progressive muscular atrophy or amyotrophic lateral sclerosis, the onset would have been comparatively rapid, followed by a cessation or even by an improvement if the patient lived. Similarly, if transverse myelitis occurs so low down as to involve the lumbar enlargement of the cord, it would cause, not spastic paraplegia with increased knee-jerk, ankle-clonus, extensor plantar reflex, no wasting, and no R.D.; but absence of knee-jerk, of ankle-clonus, and of extensor plantar reflex, with marked muscular atrophy of the legs, with R.D., paræsthesia, and bladder and rectal trouble. The involvement of the sphincters in such a case would be of considerable aid in excluding peripheral neuritis; whilst Tooth's peroneal type of progressive muscular atrophy and acute anterior poliomyelitis would be excluded not only by the paræsthesia, but also by the history of the mode of onset and the course of the malady.

A tumour involving the cauda equina is rare, but it is not altogether difficult to diagnose. It may be more difficult to determine the nature of the mass—gumma, glioma, primary sarcoma, secondary sarcoma, or carcinoma—than its site. The onset of symptoms is generally gradual, and one leg is affected either earlier than, or more than, the other. Weakness in the leg, together with severe pains both in it and in the lower part of the lumbar region of the spinal column, will be followed by muscular atrophy and R.D. Sciatica may at first suggest itself, until it is found that neither the pains nor the paresis correspond to one single nerve; and when the disease progresses and the other leg is affected, anæsthesia supervenes upon the paralysis. The site of the pain over the region of the cauda equina is an important point in the diagnosis, whilst rectal and possibly vaginal examinations are essential for the exclusion of a pelvic mass—such as carcinoma of the rectum, uterus, or ovary, a fibromyoma, a cyst, a sarcomatous, gummatous, tuberculous, or inflammatory mass—which, by interfering with the nerves at the back of the pelvis, might produce very similar symptoms. Sacro-iliac joint disease can generally be excluded by the fact that the pains are not definitely referred to the joint, whilst any wasting that might be associated with disease of that joint would not be accompanied by R.D.

Sciatica (p. 539) does not always give rise to wasting of the corresponding muscles, but sometimes it does, and occasionally it may do so bilaterally, with R.D. The localization of the pain, tenderness, and atrophy to the parts supplied by the great sciatic nerve, without affection of other nerves and muscles in the leg or calf, would point to sciatica, especially if the lesion were unilateral, and if the patient, though unable to flex his thigh to a right angle with his abdomen at the same time that he keeps his knee extended, can extend his leg backwards at the hip-joint in a way that would be impossible if he had a psoas abscess; and if he is able to bear firm backward pressure on the knee when the leg of the affected side is flexed and outwardly rotated in such a way that the foot lies across the opposite knee—a test which will exclude hip-joint disease.

When the lesion is a *thoracic aneurysm* or *neoplasm*, or an *accessory cervical rib pressing on or involving the brachial plexus*, the wasting is almost certain to affect one arm only, or one arm much more than the other, and the diagnosis will be made by physical examination of the thorax, assisted by the X rays (Figs. 440, 441, p. 544). In some of these cases the wasting may affect only certain of the muscles supplied by the median nerve, the thenar muscles wasting whilst the hypothernar muscles are still normal: this is due to the pressure of such a thing as an accessory cervical rib affecting the lower part of the cervical plexus first, and thus causing atrophy to be noticed mainly in muscles supplied from the seventh cervical segment—the thenar group.

The only *cranial nerve paralyses* that are likely to be associated with marked atrophy of muscles are those of the seventh with facial atrophy (p. 603), and of the twelfth with atrophy of the tongue (Fig. 83, p. 79).

Injuries to peripheral nerves, or inclusion of the latter in *collus*, will generally be diagnosed by the history, and by the fact that in distribution the muscular atrophy and

R.D. correspond accurately with one or more of the peripheral nerves that may have been divided or otherwise injured (Fig. 85).

Peripheral Neuritis. If all the conditions described above can be excluded, it is probable that the cause is some variety of peripheral neuritis. To merit this diagnosis, the affected muscles should be multiple and symmetrical: partial or complete R.D. should be obtained; there may or may not be sensory changes; the reflexes, both superficial and deep, are for a short time exaggerated, and then

Fig. 85.—The hand and forearm in a case of ulnar paralysis, showing particularly the 'main-en-griffe' attitude of the little and ring fingers. The photograph shows also, but less clearly, the atrophy of the hypothernar eminence and of the flexor group of muscles of the forearm.

become deficient or disappear altogether for the time being. Wasting may be extreme, but the tendency is for slow recovery to ensue, improvement beginning to set in some three or four months after the neuritis ceases. Sometimes the nature of the case is obvious, but it is often easier to diagnose peripheral neuritis than to discover its exact cause. The different conditions that may produce it are given above. In diagnosing between them the history is very important. For instance, if the patient has never been abroad *leprosy* and *beri-beri* are unlikely, whereas if he has been abroad amongst lepers, and if he has areas of anaesthesia without much paresis, with or without the characteristic nodules and bosses of subcutaneous infiltration (Fig. 388, p. 501), followed by ulceration and necrosis, the diagnosis of leprosy will at once suggest itself. The chief difficulties will perhaps be to exclude syringomyelia on the one hand and tertiary syphilis on the other. The good effects of treatment by potassium iodide and mercury may assist in detecting syphilis, and Wassermann's reaction may be positive: in syringomyelia there is little or no loss of cutaneous sensibility as there is in leprosy, though there is loss of power to distinguish heat from cold, and pain from touch. The ultimate test of leprosy would be to excise a small portion of the affected tissue and to examine it for the acid-fast leprosy bacilli.

Beri-beri is sometimes seen in this country, generally in patients who have come into

port in a ship from the East ; several of the crew have generally been affected at the same time, some may have died ; the peripheral neuritis and muscular wasting will often be associated with oedema, and there is often a history that the dietary has consisted of decorticated rice.

The presence or absence of glycosuria will serve to diagnose or exclude *diabetic neuritis*. Loss of knee-jerk in diabetes mellitus is comparatively common, but extensive peripheral neuritis is much rarer. It is associated with pain and paræsthesia as well as paresis and muscular atrophy, and it affects the limbs, especially the legs, rather than the trunk.

Gout as a cause of peripheral neuritis is always open to doubt, for often the neuritis of a gouty subject is really due to the indulgences that brought on the gout. Difficulty may also arise in attributing a neuritis to *pregnancy*, even when the patient is, or has been recently, pregnant.

In the case of *blood diseases* it is important to bear in mind that these are usually treated with arsenic, so that the peripheral neuritis may be due to the treatment rather than the disease. This will be rendered the more probable if there are or have been other symptoms of subacute or chronic arsenical poisoning, such as coryza, nausea, vomiting, abdominal colic, diarrhoea, headache, pigmentation of the skin not unlike that of Addison's disease, hyperkeratosis of the palms and soles, or herpetiform eruptions. With arsenical neuritis the limbs are involved most, particularly the legs, and there are pains and paræsthesia as well as paresis. The blood diseases may themselves cause peripheral neuritis, however, just as severe anæmias, such as pernicious anæmia, may cause degeneration in other parts of the nervous system also, notably in the long tracts in the spinal cord, with consequent sensory, ataxic, or parietic symptoms, varying with the parts involved. If the peripheral neuritis occurs early in the blood disease, the latter may not come to mind as a possibility. A blood-count is essential (p. 30). Oligocythæmia with high colour-index, no leucocytosis, a relative lymphocytosis, and the presence in blood-films of a preponderance of megalocytes, are changes characteristic of *pernicious anæmia*, in addition to which the primrose-yellow skin may be typical. Great increase in the total number of leucocytes up to anything from 50,000 to 1,000,000 per c.mm. would suggest *leucocythæmia* : if this were the splenomedullary form, myelocytes would probably be 30 per cent or more of all the white cells seen in films, whilst in the lymphatic form the lymphocytes would similarly amount to 90 per cent ; in both forms, particularly the splenomedullary, the spleen and liver would be big, whilst in the lymphatic type there would probably be general enlargement of the lymphatic glands.

Hodgkin's disease or *lymphadenoma* suggests itself when the spleen and many of the lymphatic glands are enlarged, without any characteristic blood changes—at most a simple anæmia without leucocytosis, with relative lymphocytosis, and an occasional myelocyte, basophil corpuscle, and nucleated red cell in films. *Splenic anæmia* is a doubtful entity, the name being applied when there is simple anæmia with apparently idiopathic enlargement of the spleen. Many such cases terminate as cirrhosis of the liver with ascites—Banti's disease.

Malaria will be diagnosed by the history, and by the discovery of the hæmatozoa in the blood (p. 38). The difficulty may be to exclude alcohol as a cause for the neuritis in a patient who has also suffered from severe malaria.

Infective endocarditis is sometimes so chronic and insidious that it escapes detection. Points to lay stress on are summarized on p. 46.

It may not be easy to convince oneself that some other cause of *chronic pyæmia*, whether uterine, pelvic, pulmonary, oral, or otherwise, is the cause of peripheral neuritis in a given case ; even when a general bacteriological investigation of the nostrils, posterior nares, tonsils, pharynx, mouth, tooth-sockets, sputum, urethra, urine, vagina, cervix uteri, faeces, blood, and skin has been carried out, it is often very difficult to determine whether any of the various micro-organisms discovered have really anything to do with the patient's symptoms or not. This applies particularly, perhaps, to streptococci from the mouth or from the stools, for non-pathogenic streptococci are distinguished from pathogenic varieties only by bacteriologists who are more than ordinarily skilled.

Syphilis is a doubtful cause of peripheral neuritis, especially if the patient is also

addicted to alcohol, though the discovery of a positive Wassermann reaction would suggest the need for antisyphilitic treatment.

Influenza is not to be diagnosed as the cause until every other possible explanation has been exhausted; it is too easy to attribute things to influenza. Peripheral neuritis from *typhoid fever* or from paratyphoid A or B generally arises as a direct sequel of a typical attack confirmed by Widal's tests, so that the diagnosis is not difficult as a rule. It has the same type, sensory and motor, as arsenical neuritis.

Diphtheria is one of the most important of all the causes, and if the diphtheria itself has been slight it may have been overlooked entirely, especially as the neuritis develops two or three weeks or longer after the sore throat. It is important, therefore, to lose no time in taking cultivations from the throat in all doubtful cases of peripheral neuritis; it may still be possible to find the causal organisms in swabbings. The nature of the case may be suggested at once, however, if there has been a nasal alteration in the voice, or if there is an inability to swallow liquids owing to their regurgitation through the nose—evidence of paralysis of the palate that is almost characteristic of diphtheria: the pupil reflexes are also apt to be affected, and the patient may be thought to have an error of refraction because paresis of the ciliary muscle renders accommodation difficult or impossible for the time being. The symptoms may stop at the palate and eye; but in bad cases—perhaps as the result of a toxin different from that which directly affects the palate—both paralysis and extreme atrophy of the limbs, without much sensory disorder, follow. The vagus nerves may be involved, causing tachycardia, persistent vomiting, and perhaps death; equally serious may be the involvement of the phrenic nerves, with weakness or paralysis of the diaphragm.

Fig. 86. Wrist-drop after diphtheria, similar to that of plumbism.

In regard to the various chemical substances that may produce peripheral neuritis, inquiries into the patient's occupation may assist the diagnosis. Workers amongst india-rubber come in contact with *carbon bisulphide* fumes, this compound being used to dissolve the rubber. *Naphtha* is used extensively in some trades. The use of a chemical may not always be obvious until careful inquiries are made—for instance, one may not at first see what a person who prepares rabbit skins for conversion into hats has to do with mercury, until it is learned that mercurials are used to preserve the pelts. *Mercurial neuritis* is characterized by a remarkable tremor of the hands and arms in addition to the muscular atrophy in the arms and legs; there are not many sensory symptoms as a rule. *Lead neuritis* is easily diagnosed when it causes the characteristic wrist-drop, though a similar paralysis of the hand may be due to other forms of peripheral neuritis, such as diphtheritic (Fig. 86), or to the result of compression of the musculospiral nerve by callus or crutch-head, or by sleeping with both arms across the arms of a chair 'Saturday night palsy'; in plumbic wrist-drop all the muscles supplied by the musculospiral nerve beyond the triceps become paralysed except the supinator longus and the extensor ossis metacarpi pollicis, and there is no sensory disorder: the escape of the supinator longus distinguishes wrist-drop due to plumbism from that due to compression of the musculospiral nerve, in which all the muscles are affected: the diagnosis is confirmed by finding a blue line upon the gums and the other signs of lead poisoning described on p. 45. The difficulty arises in less typical cases in which the lead causes generalized peripheral neuritis in both legs and arms, perhaps without any other symptoms, without even a blue line upon the gums if

the teeth are kept clean. The source of the lead may be very far from obvious—it may be some obscure thing, such as a hair-wash, or the result of water contamination from electrolysis in water-pipes, due to leakage of current from an electric main. In case of doubt it may even be worth while to analyse the faeces or evaporate down a large bulk of urine and apply the ammonium sulphide test for lead to the residue: a drop or two of an extract containing lead, allowed to fall into a tall glass full of ammonium sulphide, will cause a white trail to develop in the fluid as the drop descends.

Arsenical neuritis has been mentioned above (p. 83); it may arise in patients who are taking arsenic in medicinal doses, for instance for chorea or pernicious anemia; or the poison may be taken unawares, as in the Manchester epidemic, in which fatal results followed contamination of beer with arsenic; or it may have been administered maliciously with intent to murder, perhaps as weed-killer, as in not a few cases of recent years. If arsenic is suspected, a portion of hair should be sent for chemical analysis; the hair of a person taking arsenic stores the latter in proportions sufficient to allow of its detection.

In cases due to *alcohol* the pains, cramps, atrophied limb muscles, and loss of sensation and tendon reflexes result less often from periodic acute bouts than from long-continued soaking—possibly without a single actual intoxication in the popular sense—and perhaps the results are due not to the chemical substance C_2H_6O , but to other bodies associated with it. Clinically, however, it is sufficient if the diagnosis of the cause of peripheral neuritis can be narrowed down to alcohol in some form or other, and for this to be possible an accurate history is essential. The greatest difficulty arises in the case of secret drinkers, especially women who may appear to be above suspicion. The neuritis is ushered in with pains and cramps in the limbs, followed by wasting which may reach an extreme degree: the trunk and limbs sometimes look like those of a person who has been starved to death.

It only remains to add that there will always be some cases in which the cause of the peripheral neuritis fails to be found.

Herbert French.

ATROPHY, OPTIC. (See OPHTHALMOSCOPIC APPEARANCES, NOTES ON, p. 517.)

ATROPHY, TESTICULAR. When one testis is smaller than the other, it is first necessary to determine which is the normal one: for when one is slightly enlarged it may be regarded erroneously as normal and the other as too small. Some inequality may be physiological, as is the case with paired organs generally. Physiological atrophy of the testes is apt to occur in advanced life: it may begin as early as fifty, though many old men have testicles of normal size.

A testis in an abnormal position, in the inguinal canal or elsewhere, is subject not only to such causes of atrophy as may affect one normally situated, but may also be inhibited in growth from compression by surrounding parts.

The causes of atrophy of a normally situated testis may be grouped under three main headings as follows:—

1. Interference with the Blood-supply:

Compression of the spermatic cord, as by an inguinal hernia, a spermatocele, or an ill-fitting truss	Venous stasis, the result of varicocele As a sequel of operation in the region of the spermatic cord, such as those for the cure of varicocele, spermatocele, or hernia
Compression of the testicle by affections of the tunica vaginalis, such as hydrocele or hæmatocele	Elephantiasis

2. Atrophy after Orchitis or Epididymitis, due to such causes as:—

Gonorrhœa	Mumps	Gout
Tubercle	X rays	Syphilis
Injury	Typhoid fever	Influenza

3. Neurotrophic Causes, especially after injury to the brain or spine.

It has been stated that the atrophy may result from iodide of potassium: this is difficult to prove, for it seldom happens that this drug is given unless there is already some other possible cause, particularly syphilis or orchitis.

In the differential diagnosis between the above causes the history is in most instances very important.

The cause in any of the cases in Group 1 will generally be obvious. It is only necessary to bear in mind that an operation for varicocele, for instance, may have been performed successfully, and the patient may thereafter contract an orchitis followed by testicular atrophy for which the operation may be blamed unjustly.

As regards Group 2, it is very doubtful whether influenza ever really produces either orchitis or testicular atrophy. There may be a definite history of gonorrhœa, followed by orchitis, which preceded the atrophy, and then diagnosis is easy. It is to be remembered, however, that by no means every orchitis is gonococcal. If mumps, typhoid fever, gout, and injury are borne in mind, these causes of orchitis and testicular atrophy will be recognized more often than they are. Mumps is particularly apt to be overlooked; orchitis may be the sole evidence of this complaint. If the patient is seen when the orchitis is active, bacteriological examination of any urethral discharge is essential to determine whether gonococci are present or not. If gonorrhœa can be excluded, then the diagnosis of the nature of the orchitis is arrived at by considering the evidence as to gout, mumps, and so on.

It is sometimes stated that orchitis may result from strain, atrophy resulting in due course. There are cases in which, apparently as the result of great bodily exertion, especially the lifting of heavy loads or a saddle-injury during horse-riding, or falling astraddle across a fence or bar, inflammation of the testicle follows; but it is difficult to say that in these cases the strain alone produced the symptoms; there is the possibility that there may have been residual gonorrhœa in the prostate or posterior urethra, the action of the strain being merely to light up the latent inflammation. Sometimes the latent infection is not gonococcal, but due to other organisms, such as staphylococci or streptococci, whilst some believe that the *Bacillus coli communis* is the causal organism in some cases of 'spontaneous' orchitis.

There remain a number of cases, however, in which there is no clear history of orchitis, the latter having been relatively slight. Testicular atrophy will then seem to have arisen idiopathically, and it is important to remember how often it is the result of former injury, such as a kick at football, a blow from a cricket ball, contusion from falling astraddle on a fence or bicycle, and so on. The injury may date back to boyhood, many years before testicular atrophy is noticed, and it will often be difficult to prove that the latter was really due to the former.

Apart from obvious tuberculous epididymo-orchitis, transient enlargement of a testis is to be observed, if looked for, in tuberculous subjects; whether this can be regarded as a definite tuberculous orchitis or not, it sometimes results in atrophy.

The X rays are a possible cause of testicular atrophy, and all users of X rays should be careful to have a suitable lead shield. That sterility can result from repeated applications of these rays is well known, and radium emanations may have a similar result.

As regards Group 3, the history as a rule gives the diagnosis. Remarkable instances have been recorded in which, within a few months of injury to the brain or spinal cord, particularly after injury to the lumbar vertebræ, or the occipital region of the skull, the glandular elements of the testicle have disappeared. A case of Kocher's exemplifies this: A man, age 41, the father of four children, fell on his head from a considerable height. At first he did not appear to be greatly damaged, but presently twitchings occurred, and the patient became unable to work. From this time on his sexual powers diminished greatly, and his beard and pubic hair fell out. Eighteen months later this hair was gone completely, and about five years after the accident the left testicle was the size of a hazel nut, the right the size of a bean.

Herbert French.

AURA is the term applied to the immediate prelude of an epileptic seizure. It is recognized in some form or another in about 30 or 40 per cent of epileptics, and with rare exceptions always takes the same shape with every attack in each individual. An aura may be motor, sensory, psychical, visceral, or related to some special sense. A *motor* aura may be represented by an involuntary movement of a limb or a part of a limb; in other cases it takes the form of a general movement such as running. A *sensory* aura is common, and is described as a pain, a numbness, or a tingling in some part of the patient's body. A *psychical* aura is often expressed as a vague apprehension, or an indescribable feeling, or a sense of unreality. A *visceral* aura is frequent, usually as an 'epigastric sensation' or

queer feeling starting in the region of the stomach and rising to the throat, or less often as a peremptory desire to go to stool. An aura of special sense may be *olfactory*, *visual*, *auditory*, or *gustatory*; a pleasant or unpleasant odour or flavour may be perceived by the patient, or some alteration in vision may warn him of the onset of a seizure, or he may hear voices or some particular kind of sound.

The aura of epilepsy is, in relation to diagnosis, important from at least two points of view. In the first place, it often affords a clue to the particular locality in the brain from which the 'fit' or 'storm' originates and spreads. This may not be of much value in the case of idiopathic epilepsy, because there is no method at present known to us by which the seat of the disease can be treated successfully. In the case of Jacksonian epilepsy, on the other hand, the knowledge of the locality in which a fit is generated sometimes allows of benefit being obtained from surgical assistance. For instance, an aura may be the first symptom of the presence of an *intracranial growth*. A tumour of the uncinate region of the temporo-sphenoidal lobe may be revealed by the presence of signs of increased intracranial pressure and the repeated occurrence of an olfactory aura, followed by a vague, dreamy state of consciousness. A lesion of one occipital lobe may be suspected from the occurrence of epileptiform fits immediately preceded by an aura consisting of visual disturbances limited to the opposite field. An aura of pain starting in the left foot, spreading up the left side of the body, and terminating in a generalized convulsion, suggests a lesion in the post-Rolandic region of the right parietal lobe. Such instances of the importance of an aura as a localizing sign in diagnosis might easily be multiplied, but a general knowledge of the functional anatomy of the brain will suffice to supply other examples of a similar kind to the reader's mind.

In the second place, the importance of recognizing a subjective sensation as an aura, and so recognizing the existence of epilepsy in its simplest and sometimes earliest form, can hardly be over-estimated from the point of view of treatment. When a patient describes himself as being liable to subjective sensations occurring at intervals, and for which he cannot account, careful inquiry should be made as to their nature. The chief characteristics of an aura are: (1) Its spontaneous development without cause, generally during good health; (2) The suddenness of its onset; and (3) The identity of each sensation with the last. It should be understood clearly that an aura may occur alone, or may be followed by momentary loss of consciousness (*petit mal*), or by loss of consciousness with convulsions (*grand mal*). In some cases an aura may be repeated with frequency for many months before a typical epileptic seizure supervenes, and if recognized as such during this stage it is reasonable to expect that treatment will have more chance of success than at a later period, when the 'habit' of convulsions has been established firmly. The recurrence of an aura, even without further manifestations of the disease, is evidence that the morbid tendency is not controlled completely, and that discontinuance of treatment will lead to the reappearance of more serious attacks.

E. Farquhar Buzzard.

AXILLARY SWELLING. (See SWELLING, AXILLARY, p. 816.)

BABINSKI'S SIGN consists in a modification of the plantar reflex. In testing the latter the patient should be lying upon his back, with his legs very slightly flexed and each foot everted so that its outer border lies comfortably in contact with the bed or couch; the sole should be warm and dry; the ankle should be gently but firmly grasped by one of the observer's hands, to prevent the undue dorsiflexion of the whole foot which often makes it difficult to decide which way the toes themselves move, whilst the outer side of the sole is firmly and steadily stroked from the heel forwards with some such instrument as the butt end of a pencil. In healthy adults the big toe and the other toes will become plantar-flexed; when the great toe becomes dorsiflexed instead, it presents the extensor plantar reflex, or Babinski's sign. Whichever way the other toes move, it is with the direction of movement of the big toe alone that Babinski's sign is concerned, and it sometimes simplifies the test if the four outer toes are held so that the big toe alone is left free to move. If Babinski's sign is present the fact is usually ascertained with ease; when there is any doubt as to which way the great toe moves, the plantar reflex is seldom really extensor.

The great value of the sign is in distinguishing between functional and organic affections of the nervous system. If the patient is a fully conscious adult with paresis

of one or both legs, the existence of an extensor plantar reflex is proof that the lesion is organic. The converse is not true: for with tabes dorsalis, and with lower neuron affections such as infantile paralysis, Tooth's peroneal type of progressive muscular atrophy, peripheral neuritis, Landry's acute ascending paralysis, and primary muscular dystrophies, the plantar reflex is flexor if it is obtainable at all.

Babinski's sign is seen best when there is a lesion in the crossed pyramidal tract. Thus it is present in cases in which tumour, abscess, hæmorrhage, thrombosis, or embolism has caused hemiparesis or hemiplegia by affecting either the pyramidal cells themselves in the motor cortex or the pyramidal fibres in the internal capsule: in cases of cerebellar tumour, owing to the fact that this, by compressing the medulla, may lead to lateral sclerosis in the cord; and in cases of disseminated sclerosis, transverse myelitis either primary or due to compression, ataxic paraplegia, Friedreich's ataxy, amyotrophic lateral sclerosis, primary lateral sclerosis, some cases of syringomyelia, combined sclerosis of the cord, and in those cases of irregular sclerosis of the cord that may be associated with severe oligocythæmias such as pernicious anæmia. The differential diagnosis of these conditions will be found under HEMIPLEGIA (p. 381), PARAPLEGIA (p. 621), and elsewhere. Babinski's sign is not found in those cases of hysteria that sometimes simulate one or other of the above conditions: provided always that the patient is a conscious adult. This proviso is important, because the plantar reflex may be extensor without there being any decided changes in the cord or brain in infants and quite young children: also in a considerable proportion of older children suffering from *chorea*: and also sometimes in adults during deep sleep, or under conditions of unnatural unconsciousness such as that due to a general anæsthetic, or acute alcoholic intoxication, or such affections as epilepsy, uræmia, concussion, saturnine encephalopathy, and in some other forms of coma. These exceptions, however, scarcely detract from the great value the sign has as a means of distinguishing between organic and functional paralysis of the legs of the upper neuron type.

Herbert French.

BACILLURIA. (See BACTERIURIA, *infra*.)

BACKACHE.—(See PAIN IN THE BACK, p. 526; and PAIN IN THE PELVIS, p. 572.)

BACTERIURIA (see *Figs. 87-92*) is a comprehensive term employed to indicate that the urine when freshly voided contains micro-organisms. *Bacilluria* is a term of similar import, but is restricted to those cases in which rod-shaped bacteria are present. The vaginal segment of the female urethra and the anterior portion of the male urethra are normally inhabited by certain non-pathogenic bacteria (chiefly cocci, such as *Streptococcus brevis*, *Staphylococcus albus*, also varieties of *Bacillus aerosis*, etc.), which are, of course, present in urine obtained under ordinary conditions, and so constitute what may be termed physiological bacteriuria. Bacteriuria as a pathological condition due to some lesion of

urinary system posterior to the urethra can only be recognized with certainty by the examination in the laboratory of a catheter specimen of the urine collected with the most scrupulous attention to asepsis: for, on the one hand, a perfectly clear acid urine may be heavily loaded with bacteria, and, on the other, a urine may owe its turbidity either to purely physico-chemical causes, or to growth in it of bacteria which have gained access after its exit from the urethra. Moreover, although the identity of the infecting organism may be suspected from general clinical considerations, cultivation experiments are essential in order to settle the matter beyond doubt.

Bacteriuria may be persistent and may indicate either general or local infection. It is a rare symptom of general infection, save one of such intensity that an acute nephritis, associated with a definite hæmaturia, has supervened. Usually its appearance indicates a local infection of the urinary tract: it then occurs with greatest frequency in young children and pregnant women, when the micro-organism concerned is usually *B. coli*, and the site of the infection the pelvis of the right kidney. It is, however, met with at all ages and in both sexes, and many different bacteria have been recorded as the causative factors: and whilst the infection is commonly due to some particular micro-organism, the possibility of multiple infection must not be forgotten—the most usual being a double infection due to *B. coli communis* and *Str. pyogenes longus*.

When intermittent, bacteriuria may indicate a general infection, or a local infection

Figs. 87-92.—MICROSCOPICAL FIELDS IN FILM PREPARATIONS OF THE PURULENT DEPOSIT OBTAINED BY CENTRIFUGALIZING THE URINE IN CASES OF BACTERIAL INFECTIONS OF THE URINARY TRACT

of some area distant from the urinary tract, as, for example, a tonsillitis or a dental abscess, and often in an obscure case of pyrexia a bacteriological examination of the urine will well repay the trouble involved. Intermittent bacteriuria, particularly of the staphylococcal type, is often associated with kidney calculus, and it is also not uncommon in cases of rheumatoid arthritis.

Bacteriuria may be a symptom in :—

1. General Infections, with or without associated nephritis, due to :—

Streptococcus pyogenes longus	Staphylococcus pyogenes	B. coli communis
Pneumococcus	aureus	B. typhosus
Gonococcus	Micrococcus tetragenus	B. paratyphosus
	Micrococcus melitensis	

2. Local Infections :—

Nephritis, pyelonephritis, or ureteritis due to :—

B. coli (Fig. 92)	B. pneumoniae (Friedländer's bacillus)	Staphylococcus pyogenes aureus
B. tuberculosis (Fig. 87)	Streptococcus pyogenes longus (Fig. 89)	Pneumococcus
B. pyocyaneus		

Cystitis due to :—

B. coli	B. typhosus	Staphylococcus pyogenes aureus (Fig. 90)
B. tuberculosis (Fig. 88)	B. pneumoniae (Fig. 91)	
	Streptococcus pyogenes longus	

Prostatitis due to :—

B. coli	Staphylococcus pyogenes aureus	Streptococcus pyogenes longus
Gonococcus		

Urethritis due to :—

Gonococcus	Pneumococcus	Micrococcus catarrhalis
Staphylococcus aureus or albus	Streptococcus pyogenes longus	

In the above table the various micro-organisms are, speaking generally, arranged in the order of their frequency.

Finally, a slight and transitory bacteriuria due to *B. coli communis*, and one usually passing off without any treatment, can frequently be observed following operative measures upon the rectum or anus, or the organs of generation.

In general infections the urine is either normal in appearance, or by reason of its admixture with blood may present any tint from 'smoky' to bright red. The reaction is usually acid; often a degree of acidity is recorded which if present in an artificial culture medium would inhibit the growth of the infecting micro-organism. Albumin is present, varying in amount from a trace to 7, 8, or more parts per thousand, and microscopical examination of the centrifugalized deposit shows blood-cells, renal tube-casts, and renal epithelium, in addition to the infecting bacterium. The clinical symptoms presented by patient are those of the general systemic infection.

In local infections of the genito-urinary tract where infection is due to one species of micro-organism only, the urine presents a somewhat similar appearance; blood, however, may be entirely absent, while pus when measured by the centrifuge may vary in volume from a trace to 10 or 20 per cent of the total bulk of urine. In the early stages of a local infection, however, microscopical examination of the deposit may merely show the presence of leucocytes slightly in excess of normal, so that without the use of the microscope the fact of pyuria may easily be missed altogether.

Occasionally, and particularly in adult cases, it may be noted that the urine passed during the day is neutral or faintly alkaline—the change in reaction then being due to physiological causes. In those cases where the urine is strongly alkaline the alkalinity is due to ammonia resulting from the decomposition of urea, not by the pathogenic infecting organism but by non-pathogenic saprophytes which have gained access to the urine, either after it has been voided or whilst still *intra vesicam*. In the latter instance the contamination may have taken place as a result of careless instrumentation, or (as in the female) by continuity of surface, but it also frequently occurs owing to the passage of micro-organisms through the inflamed bladder wall from the lumen of the adjacent large intestine.

The clinical symptoms associated with bacteriuria due to local infection vary enormously with different patients. Frequency of micturition, scalding, dull aching pains in one or both loins, with tenderness on deep pressure over the kidney or ureters, pains in the perineum and hypogastrium (according to the situation of the primary infection), severe rigors, pyrexia (*Fig. 448*, p. 560), anorexia, nausea, and vomiting are amongst those commonly observed. It is important to remember its relatively common occurrence in children, in whom there may be hardly any symptoms at all, or perhaps general delicacy or ill health, or gastro-intestinal disturbance, without any special urinary symptoms attracting notice. The urine generally contains only a trace of albumin and no obvious pus; the diagnosis then depends upon bacteriological investigation of a catheter specimen, the need for which will be suggested by the discovery of a decided excess of leucocytes in the centrifugized deposit from the specimen first collected during the routine examination of the patient. *Jno. Eyre.*

BALDNESS. Alopecia, or baldness, may vary in degree from slight thinning to complete loss of the hair. There are four main varieties of baldness or alopecia, namely: (1) *Congenital*, (2) *Senile*, (3) *Premature*, and (4) *Alopecia areata*.

1. **Congenital Alopecia** is seldom complete, and the hair may be lanugo-like. In the latter case the diagnosis is certain, as it also is when the baldness is accompanied by developmental defects in the skin or its appendages. When there is complete absence of the hair, not only of the head but also of the eyelids, face, trunk, armpits, and pubic regions, the diagnosis is obvious. It may be associated with dwarfism and premature senility (*Fig. 201*, p. 237).

2. **Senile Alopecia** needs no description. The age of onset may be reduced by the constant wearing of a hard-brimmed hat stopping the proper circulation to the top of the scalp, resulting in baldness of the top of the head but an abundance of hair below the hat-brim level; this applies to males far more than it does to women.

3. **Premature Alopecia** may be (a) idiopathic or (b) symptomatic. The former, much less frequent than the latter, and due to no recognizable cause except heredity, usually begins between the ages of twenty and thirty-five; in many cases at the vertex, like senile baldness, but often at the temple, when it extends backwards elliptically. Symptomatic premature baldness may be either temporary or permanent, gradual or rapid, and is dependent upon a great variety of local or constitutional causes, including *seborrhoea* of the scalp, *psoriasis*, *chronic eczema*, *crispipelas*, *ringworm*, *favus*, *lupus erythematosus*, *syphilis* (*Fig. 93*); it is also a sequela of fevers or other acute systemic diseases, and sometimes of a severe shock to the nervous system such as may result from a sudden and unexpected bereavement or the like. When it

Fig. 93. Partial alopecia due to tertiary syphilis. The sallow pigmented skin is also suggestive of the underlying malady. The Wassermann reaction was strongly positive. The patient had lost nearly all his hair on several occasions, but it grew again when anti-syphilitic treatment was given.

such as may result from a sudden and unexpected bereavement or the like. When it

occurs as a sequel to fevers, in syphilis, ringworm (except after severe kerion), erysipelas, and eczema, the loss of hair is usually but temporary: in seborrhœa, favus, lupus erythematosus, morphœa, and *folliculitis decalvans*, it is generally permanent: it is always so when the hair-follicles have been destroyed.

The most important form of symptomatic baldness is that which is associated with seborrhœa, whether of the oily or of the dry kind. The exfoliation of dry epidermic scales which characterize the latter, and is attributed by Sabouraud to the action of the 'bottle bacillus', is often known as *pityriasis alba*. Seborrhœic alopecia has the same distribution as idiopathic baldness.

4. **Alopecia areata**, in which the hair falls out in more or less circular smooth white patches, is generally of irregular distribution. Usually the patches continue to spread for a time, and may run into others, denuded areas of irregular outline thus being formed, with a surface white and smooth as a billiard ball. The hairs at the edges of the patches are looser than the others, and among them may be seen short stumps that have atrophied close to the root, so that they resemble a note of exclamation (!). In rare cases the hair falls out not in patches but more generally and very rapidly: and soon the whole scalp may be denuded, and even the hair of the whole body may be lost, and with it the nails of the fingers and toes. The affection with which alopecia areata is most easily confounded is *ringworm* of the trichophytic variety: the differential diagnosis between the two affections will be found under FUNGUS AFFECTIONS OF THE SKIN (p. 309). Alopecia areata may also be confused with another form of symptomatic baldness, namely, *alopecia cicatricata*, the *pseudo-pelade* of Brocq, in which depressed islands of baldness, round or of irregular shape, occur on the scalp, the patches usually spreading and coalescing into large, smooth, shiny areas: these are cicatricial: there is destruction of the follicles so that the hair is never restored: there are normal-looking hairs on the bald areas, and the note-of-exclamation stumps of alopecia areata are absent. The same diagnostic features, with the addition of a circumpillary ring of inflammation, apply to *folliculitis decalvans*. The bald patches sometimes met with in *secondary syphilis* may be distinguished from those of alopecia areata by the co-existence of other syphilitic symptoms, by the positive Wassermann serum reaction, and by the effects of specific treatment. The bald areas of *lupus erythematosus* are in greater or less degree cicatricial, there is destruction of the follicles, and a border which is slightly or distinctly inflamed. Ernest Dore.

BEARING-DOWN PAIN.—(See PAIN, BEARING-DOWN, p. 529.)

BLACK SPECKS BEFORE THE EYES are of two types: (1) *Moving*, (2) *Fixed*.

1. **Moving Black Specks** are practically always due to *muscæ volitantes*. The aqueous and vitreous humours are not absolutely homogeneous: in both there are minute particles in most persons, and these throw shadows upon the retina which are referred by the patient to points in the visual field outside him. They seem to be in front of his eyes, interfering with what he wishes to look at: yet when he tries to locate them definitely by looking directly at them, they immediately float away, as it were, from his direct field of vision to a peripheral part. He can never focus them, and yet he may be conscious of seeing them some time. Only few persons in perfect health are troubled in this way, for although *muscæ volitantes* may be present all the time, the mind neglects them and fails to notice them. When the eye is tired by close work, however, or the patient is suffering from brain-fag, worry, insomnia, biliousness, or other similar condition, they may attract his notice very much and make him fear that he is developing some serious lesion such as a cataract. Microscopists often find them a great nuisance. After a rest or a holiday they will cease to obtrude themselves upon the patient's notice, but he will notice them again when he gets overworked or run down. In a similar way *muscæ volitantes* may be troublesome in those who are suffering ill health due to almost any organic cause, especially if it is associated with anæmia. The way in which the specks float away when an attempt is made to focus them is characteristic.

2. **Fixed Black Specks.**—When, on the other hand, the patient notices a black spot or spots in his field of vision, always present and always in exactly the same relationship to the point upon which he is focusing his eye—not floating away into different parts of the field of vision like *muscæ volitantes*—a careful examination of the eye with the ophthalmoscope, assisted perhaps by the perimeter to map out the abnormal blind spot with

accuracy, will generally reveal some organic lesion in the eye to account for them. An opacity in the cornea from old *keratitis*, or synchia from adhesions due to old *iritis*, or a *cataract*, may be seen, or tiny white patches at the macula indicative of incipient *albuminuric retinitis*, of grave omen; or a small *detachment of the retina*; or a *melanotic sarcoma* of the eyeball; or *early optic neuritis*; or a *thrombosed retinal vein*; or an *embolized branch of a retinal artery*; or a *hemorrhage* into the vitreous; or a *scotoma* from localized *optic atrophy*, such as is met with sometimes in cases of *disseminated sclerosis*; or an early stage of *tobacco amblyopia*, or the amblyopic effects of certain drugs, especially *quinine*. Special ophthalmic experience will be needed to diagnose between these different conditions, although the ophthalmoscopic appearances (p. 517) of some of them are pathognomonic.

Herbert French.

BLEEDING GUMS.—A spongy, bleeding condition of the gums, attaining such a degree that the teeth become covered by the exuberent blood-oozing tissues, was a prominent feature of *scurvy*, a serious and often fatal disease which used to be common on sailing ships when fresh food was necessarily absent from the diet for weeks or even months at a time. It is now rare in its full development, but is still found in a mild form amongst children—infantile scurvy, or Barlow's disease—as the result of long-continued feeding with tinned milk without fresh food. Its chief features are anæmia and tenderness of the long bones due to hemorrhages under the periosteum; in severer cases, besides sponginess and bleeding of the gum with more or less general stomatitis, there may be purpura and other hemorrhages. The diagnosis is suggested by the diet history, and confirmed by the benefit that follows the addition of fresh milk, and, in older children, fresh vegetables. A similar condition may arise in adults whose circumstances compel them to live on tinned foods. There are, however, many other causes of bleeding of the gums besides scurvy. The differential diagnosis is generally easy, but sometimes very difficult. The first point to determine is whether the gum condition is due to local changes only, or whether it is part of a more general condition.

1. Bleeding Gums due to General Conditions or preceded by Lesions elsewhere than in the Mouth:—

Scurvy	Purpura	Febrile or asthenic states
Splenomedullary leukaemia	Syphilis	accompanied by sordes, e.g.,
Lymphatic leukaemia	Mercurialism	pneumonia, typhoid fever,
Hodgkin's disease	Iodide poisoning	the later stages of malignant
Pernicious anæmia	Phosphorus poisoning	cachexia, general paralysis,
Aplastic anæmia	Arsenic poisoning	acute yellow atrophy of the
Splenic anæmia	Lead poisoning	liver, and so forth
Hæmophilia		Dyspepsia

2. Bleeding Gums due to purely Local Conditions:—

Injury, e.g., by tooth brush	Actinomycosis	Gangrenous stomatitis
Dental caries	Acute or chronic stomatitis	(cancerum oris, phagedæna oris, noma oris)
Tartar	not obviously due to any of the causes already mentioned, e.g.:	Tuberculous gingivitis
Pyorrhœa alveolaris		Erythema bullosum, dermatitis
Papilloma	Aphthous stomatitis	herpetiformis, pemphigus,
Epulis	Ulcerative stomatitis	affecting the mouth as well as the epidermis
Myeloid sarcoma	Vincent's angina	
Epithelioma		

1. BLEEDING GUMS DUE TO GENERAL CONDITIONS.

Many of the above conditions are discussed under other and more prominent symptoms, so that here we need refer to them but briefly (see SPLEEN, ENLARGEMENT OF, p. 774; ANÆMIA, p. 25; PURPURA, p. 675; etc.). A blood-count is required to diagnose or exclude *leukæmia* or *pernicious anæmia*. The family history may suggest *hæmophilia*. *Splenic anæmia*, *Hodgkin's disease*, and *aplastic anæmia* attract attention more on account of the enlargement of the spleen or of the lymphatic glands (p. 471), or of the anæmia, than because of spongy gums. *Purpura* is itself a symptom and not a disease.

Syphilis, particularly in its secondary stage, may produce stomatitis, pharyngitis, laryngitis, and gingivitis, with bleeding, even when no mercurial treatment has been adopted; the secondary roseola may still be present, or the history may be obvious.

Difficulty arises mainly in women and children, and when the chancre has been extragenital (Fig. 94). Wassermann's serum test may be tried, or the *Spirochæta pallida* looked for in scrapings from the mucous lesions.

Mercury is very liable to cause profuse salivation and acute stomatitis, with distressing and painful swelling of lips, gums, tongue, and cheeks: swallowing may become impossible, the glairy saliva hangs in strings from the protruding tongue and bulging lips, the mucosa bleeds on the slightest touch, and the patient is the picture of abject misery. Some

Fig. 94. Primary syphilitic sore on the lower lip.

persons are far more intolerant of mercury than others, but its worst effects have occurred when the remedy has been employed when the teeth are carious or the mouth unclean, and when there is albuminuria (syphilitic nephritis). The diagnosis depends upon a knowledge of the drugs that are being given or, in occupation cases, of the chemicals that the patient has been working with.

Iodides may cause profuse coryza, due to conjunctival, nasal, and oral catarrh, but the amount of bleeding that accompanies it is slight. The nature of the drugs being taken will suggest the diagnosis, or if there is doubt as to the drugs, the urine may be tested for iodides.

Phosphorus used to produce very severe stomatitis, going on to necrosis of the jaw—'phossy jaw'—not infrequently ending in death as the result of fatty degeneration of the liver and heart: this is uncommon since restrictions have been laid upon the use of crude yellow phosphorus in the manufacture of matches. The occupation generally serves to suggest the diagnosis, though the patient may have been taking a rat paste or other vermin-killer containing phosphorus with suicidal intent.

Arsenic and *lead* are both rare causes of bleeding gums: occupation, or medical prescription, habits as regards drinking, or the possibility of arsenical administration in the form of weed-killer with murderous intent, may suggest the diagnosis, and there may be other signs of the poisoning, particularly pigmentation of the skin, vomiting, diarrhoea, hyperkeratosis of the soles and palms, and generalized peripheral neuritis in the case of arsenic: and the symptoms given elsewhere (p. 45) in the case of lead. Arsenic may be found in excess in the hair, or lead may be detected in the fæces or in the residue from a bulk of urine.

Febrile and *asthenic* states only cause sordes and bleeding gums when the patient has already been ill some while, or when the nursing has been remiss: the diagnosis will depend on symptoms other than those connected with the gums.

2. BLEEDING GUMS DUE TO LOCAL CONDITIONS.

When care has been taken to exclude general causes of bleeding of the gums, differentiation between the various local causes is not difficult. Some patients are alarmed by a symptom, when its cause is nothing more than the use of a *new tooth-brush* whose bristles have slightly lacerated gums that are accustomed to an older and softer brush. The history will indicate other forms of local injury—an ill-fitting tooth-plate, perhaps. *Hæmoptysis* may be simulated.

Dental caries may be obvious, or it may be hidden away between adjacent teeth and yet be irritating the gum enough to cause it to bleed with undue readiness when the teeth are brushed. *Tartar* is obvious on inspection. *Pyorrhœa alveolaris*, also known as *suppurative gingivitis* or *Rigg's disease*, is the result of septic infection extending down into the sockets, loosening the teeth, causing the gum margins to recede by erosion, and leading to a purulent discharge from between the gums and the teeth. This condition may be present even when the external aspect of the teeth seems perfect: a very fine probe may sometimes be passed painlessly down into the tooth-socket between adjacent teeth where the suppurative process has been progressing unsuspected, and out of the reach of the tooth-brush. An X-ray examination may be required to determine the condition of the submucosal portions of the teeth (Figs. 61-63, p. 43). The gums bleed on the slightest touch in severe cases, the breath is foul, and the constant swallowing of pyogenic organisms and their products leads to dyspepsia, anæmia, chronic ill health, listlessness, functional nerve disorders, and sometimes more acute symptoms of general pyæmia,

especially pyrexia and perhaps multiple infective synovitis and arthritis. Neurasthenia and depression ultimately ensue in many cases, and sometimes very severe and even fatal anaemia or purpura.

The diagnosis of *alveolar abscess* is generally obvious, though infection of a *benign* or *malignant new growth* may simulate it for a time. Microscope examination of the excised tumour is the only certain way of diagnosing the nature of an odontoma, papilloma, simple epulis, myeloid sarcomatous epulis, or epithelioma of the gum.

Actinomyces is rare in man; but the jaw, gum, or cheek are parts most commonly affected. The chronic nature of that which partakes of the characters partly of a neoplasm and partly of an abscess, in a person who has had occasion to put straws, cotton, or other vegetable products into his mouth, may suggest the diagnosis, which will be confirmed by the finding of the ray fungi in the purulent discharge, or in sections from parts excised. Minute grey or yellowish specks in the pus are said to be characteristic, but they are not always seen, and it is by microscopical examination that the diagnosis is made with certainty (see Fig. 610, p. 779).

Stomatitis in its various degrees may have a general cause, such as mercurialism (see above); or it may be due to purely local infection with micro-organisms. It might perhaps be classified bacteriologically—the variety spoken of as thrush being due to *Oidium albicans*, for instance; other cases being due to different organisms such as *Streptococcus longus hemolyticus*, *Streptococcus viridans*, the *Spirilla* and *Pacilli fusiformes* of Vincent, the *pneumococcus*, Friedländer's *pneumobacillus*, *Staphylococcus aureus*, Pfeiffer's *Bacillus influenzae*; whether the *Amoeba buccalis* or any of the various *Streptothrix* species which are often found to be present are causal or merely concomitant is undetermined; and in any case it requires very considerable acumen on the part of the bacteriologist who makes cultures to say which of the many organisms that turn up in the cultures is really the cause of the condition: this is particularly true of the streptococcus group. Clinically stomatitis is classified by its degree into acute catarrhal, ulcerative, and gangrenous. All these affect the mucosa of the cheeks, lips, tongue, and palate, in addition to the gums, and any of the inflamed parts bleed readily. The first degree is characterized by redness, swelling, tenderness, and pain, with inability to move the tongue about in order to eat and swallow, swelling and protrusion of the lips, foulness of the breath, and very often salivation. There may or may not be localized greyish or white aphthous patches; these are commoner in children. When ulcers occur, these are generally multiple and shallow, very painful, with more or less glazing of the ulcerated surface, and acute hyperaemia of the margins. The gangrenous form is better known as *cancrem oris* (Fig. 95), fortunately rare, though sometimes seen in ill-cared-for children who have contracted measles or some other acute debilitating fever. The cheek is affected first, a dusky-red or black spot appearing within and without, spreading rapidly and leading to sloughing and perforation of the cheek, gangrene of the gums and jaw, falling out of the teeth, a very foul nauseating odour of the breath, and death from utter exhaustion.

Fig. 95. *Cancrem oris*.

Tuberculous gingivitis is rare, but when it does occur it is very severe. The nature of the bleeding gums will be suggested by the co-existence of phthisis, and tubercle bacilli may abound in smears from the gum.

Erythema bullosum, *dermatitis herpetiformis*, and *pemphigus*—particularly the first—may affect mucous membranes as well as the skin, especially the mouth, colon, and vagina. The result as regards the mouth is very distressing; the crusts and resultant inflammation of lips, gums, tongue, cheeks, palate, fauces, and pharynx may make it impossible for food

to be taken orally, and the patient loses weight rapidly and becomes very ill. The mucous membrane everywhere bleeds on the slightest touch, and the condition is pitiable. There is generally pyrexia. The diagnosis is, as a rule, easy, for the mucous membranes are seldom attacked unless the skin is affected also (see BULLÆ, p. 123, and EOSINOPHILIA, p. 271). Herbert French.

BLOOD IN THE URINE. (See HEMATURIA, p. 347.)

BLOOD PER ANUM.—The passage of blood per anum may be : (I) *Obvious to the patient because the blood is still of its recognizable red colour, or so little changed that it is still apparent as blood.* (II) *Obvious to the doctor, but not to the patient, when the blood has come from sufficiently high up for it to have become so changed as to be black instead.* **MELÆNA** (p. 481). (III) *Not obvious either to the patient or to the doctor, yet recognizable when laboratory tests for blood are applied to the faeces—a condition spoken of as occult blood in the stools.*

1. OBVIOUS RED BLOOD PASSED PER ANUM.

The following list includes most of the conditions under which this may be found :—

1. From Anal Causes—

Piles	Fissure	Fistula	Foreign body
-------	---------	---------	--------------

2. From Rectal Causes :—

Carcinoma, primary	Infective proctitis	pelvic sarcoma, pelvic abscess, actinomycosis, Bilharzia haematobia
Polypus	Invasion of the rectum by the following : Vesical carcinoma, uterine carcinoma,	
Syphilitic ulceration		
Tuberculous ulceration		

3. From Colonic Causes :—

Carcinoma, primary, of sigmoid colon, descending colon, splenic flexure, transverse colon, hepatic flexure, ascending colon, caecum	Intussusception Amoebic dysentery Bacillary dysentery Acute non-ulcerative colitis Ulcerative colitis Actinomycosis of the caecum Thrombosis of mesenteric vein Embolism of mesenteric artery	Injury : (a) Abdominal ; (b) Per rectum, e.g., after sigmoidoscopy Acute summer diarrhoea of infants After irritant drugs : Arsenic, phosphorus, calomel, excessive purgation Oxyuris vermicularis
Chronic diverticulitis		
Acute diverticulitis		
Polypus of the colon		
Tuberculous ulcers of the colon		

4. From Causes in the Ileum :—

Intussusception	Thrombosis	After birth, if the stump of the umbilical cord becomes infected
Typhoid fever	Embolism	
Dysentery	Injury	

5. From Causes in the Jejunum :—

Peptic ulcer	After gastrojejunostomy
--------------	-------------------------

6. From General Infective or Allied Causes :—

Cholera	Intermittent fever (severe)	Blood diseases : Pernicious anaemia, splenomedullary leukaemia, lymphatic leukaemia, purpura (q.v.)
Yellow fever	Relapsing fever	Jaundice (q.v.)
Sprue	Scurvy	
Typhoid fever	Septicæmia	

7. From Duodenal Causes :

Simple ulcer	Injury	Carcinoma (very rare)	Ankylostomiasis
--------------	--------	-----------------------	-----------------

8. From Gastric Causes :

Simple ulcer	Injury	Carcinoma	Sarcoma
--------------	--------	-----------	---------

9. From the Esophagus :

Cirrhosis of the liver

10. From Swallowed Blood due to :

Epistaxis (q.v.)	Hæmoptysis (q.v.)	Ruptured aneurysm
------------------	-------------------	-------------------

It is clearly unnecessary to discuss each and all of the above conditions in detail : in many the blood per anum will be but a minor item in the course of some illness whose nature is indicated by other and more characteristic symptoms. When the source of bleeding has been high up in the alimentary canal gastric ulcer, gastric carcinoma, duodenal ulcer, cirrhosis of the liver : or when the blood has been swallowed, from epistaxis, hæmoptysis, or a leaking aneurysm the blood generally becomes so altered by the digestive juices that, by the time it is passed per anum, it is no longer red but black, and the differential diagnosis of the causes of black altered blood passed per anum is discussed in the article on *MELÆNA* (p. 181) : but it is worthy of note that sometimes the quantity of blood lost in conditions which usually cause melæna may be so great that it reaches the anus undigested and is passed not as black tarry motions but as blood still recognizable by its red colour. The other symptoms in such cases, however, generally indicate that the bleeding is from higher up than the colon or ileum.

When definite blood, recognizable by the patient, is passed per anum and there is no general pyrexial illness—typhoid fever for example, or infective endocarditis, or some abdominal catastrophe, such as direct injury, or the effects of thrombosis or embolism—to account for it, the chief point that next arises for decision is : Does the blood come from piles or other local anal lesion, or is its source a more serious, and perhaps even grave, lesion higher up ? It is seldom safe to assume that blood per anum is due merely to piles : careful local examination, even perhaps to the extent of using the sigmoidoscope, is often required to avoid the error of attributing to simple piles that which is really caused by a rectal carcinoma in an operable stage, but soon to become inoperable if the case is allowed to drift.

With *piles, fissure, or fistula* the bleeding is generally such that the blood is passed unmixed with the faeces, and it is not as a rule associated with much mucus : with lesions of the pelvic colon, or of parts higher up, there may be no mucus, but when mucus is passed as well as blood the lesion is generally something more than piles. If the blood is mixed with the faeces rather than passed as drips after the motion has been evacuated, the lesion is generally more serious than piles, though the converse is not true, for a rectal carcinoma or a polypus may lead to blood passing in drips or even in gushes quite separate from faeces. There is no invariable rule to follow : no case in which blood is passed per anum can be regarded as unimportant until careful examination—visual, digital, if necessary instrumental—has been made to exclude the more serious troubles.

In adults, the chief lesions to diagnose or exclude are the following :

1. Malignant Disease :

Carcinoma of the rectum	Carcinoma of the descending colon
Carcinoma of the sigmoid colon	Carcinoma higher up

2. Polypus :

Single pedunculated polypus of the rectum	Single pedunculated polypus of the colon
Single pedunculated polypus of the sigmoid colon	higher up
	Multiple polypi of the rectum or pelvic colon

3. Non-malignant Ulceration :

Syphilitic, venereal, or septic ulceration of the rectum	Ulcerative colitis
Tuberculous ulceration of the rectum	Dysentery : (a) Amœbic, (b) bacillary

1. Malignant Disease.—Digital examination of the rectum is essential; by its means one may often diagnose the existence of trouble more serious than piles. *Rectal carcinoma* may be obvious to the finger; or a typical *rectal polypus* may be felt; *venereal* or *septic* ulceration of the rectum may be less obvious as to its nature, but it may sometimes be distinguished from carcinoma by the fact that it generally starts immediately above the internal sphincter, whereas with carcinoma there is usually an inch or more of normal mucosa above the sphincter before the neoplasm is reached. The remaining conditions generally require more elaborate investigation for their diagnosis, notably by means of the proctoscope, the sigmoidoscope, X rays after an opaque enema, and microscopical and bacteriological examinations. The need for these will be indicated by such additional symptoms as true diarrhoea, spurious diarrhoea (i.e., frequent desire to go to stool but with comparatively little result), pain, constipation, loss of weight, anaemia, or general ill health. *Carcinoma of the sigmoid colon* may be seen with the sigmoidoscope.

Carcinoma of the descending colon or of the colon higher up may be suggested by the passage of blood and mucus per rectum associated with increasing constipation, and discomfort or pain in the left iliac fossa; a tumour may be felt in the left iliac fossa, but the growth may be too high up for the sigmoidoscope to reach it. Bismuth and X-ray examination may serve to demonstrate stenosis of the bowel at the site of the growth; and if the condition should be *chronic diverticulitis* and not carcinoma the fact will be made clearer by operation than in any other way.

2. Polypus.—*Single polypi* of the rectum or of the colon higher up may sometimes be very difficult to feel with the finger, but they may be detected with the sigmoidoscope when they are not too high up. Their pedicle is often an inch or more in length, and no thicker than string; the globular distal end of the polypus is apt to become inflamed and to bleed; there may be no pain and no diarrhoea to call attention to the site of the bleeding and one is apt to attribute the hamorrhage to internal piles. The patients sometimes lose so much blood progressively that their appearance simulates pernicious anaemia; some may be regarded, erroneously, as instances of some primary blood disease with general bowel hamorrhages, when sigmoidoscopy might reveal the polypus and removal of the latter might cure both the bleeding and the anaemia.

Multiple polypi of the rectum or pelvic colon cause constipation with the passage of bloody mucus rather than profuse hamorrhage, and they tend to simulate rectal carcinoma. They may be felt digitally per rectum, or may be higher up and need the sigmoidoscope for their detection. Sometimes they are flat and sessile; occasionally they may project like stunted fingers, and be so numerous as to produce partial intestinal obstruction by becoming tangled together. They are uncommon, but it is a great relief when operation is performed for their removal, and the condition, thought primarily to be malignant, turns out to be thus simple.

3. Non-malignant Ulceration. Non-malignant colitis, with or without ulceration, is of all degrees from mild, temporary, superficial, to severe, intractable, persistent, and fatal. There is no real line of distinction between ulcerative colitis as it occurs in England, and chronic dysentery arising abroad; but for the sake of convenience dysentery is a term generally employed for cases that derived their infection from or in the tropics, ulcerative colitis being the term used to designate corresponding states of affairs that are not known to have had a tropical origin.

As regards the tropical dysenteries, instances of which may arise in England even in patients who have never been abroad, there are two main types, namely: (a) Amœbic dysentery; and (b) Bacillary dysentery. The distinction is important in connection with treatment, amœbic dysentery being curable by subcutaneous injections of emetine hydrochloride or by giving bismuth-emetine-iodide by the mouth; bacillary dysentery being influenced little by emetine, but helped towards cure by serum injections—Shiga's or Flexner's as the case may be. The amœbic form, moreover, is by far the more likely to be followed by tropical amœbic abscess of the liver.

Both forms present every degree of severity; there may have been no acute beginning, the patient suffering from little worse than mild diarrhoea; on the other hand, the illness may start violently with severe abdominal pains, pyrexia, tenesmus, and constant running diarrhoea succeeded by the repeated passage per rectum of blood-stained mucus or pure blood at frequent intervals. The acute phase may be fatal; or complete cure may be

brought about in a week or two ; or there may be temporary improvement followed by a relapse or several relapses, ending in gradual recovery ; or, instead of complete cure, a condition of chronic dysentery with persistent ulceration of the colon may supervene, this being the state of affairs met with in cases who have returned, uncured, from the tropics. The symptoms are then precisely similar to those of English ulcerative colitis.

There may be chronic diarrhœa, six or seven motions being passed daily with more or less abdominal griping and tenesmus, the stools being accompanied with mucus and at times with blood ; or blood and mucus may be evacuated on some occasions without faecal matter, or the patient may pass pure blood from time to time without mucus or faeces. Sometimes there are quiescent intervals of weeks or months, with stools that may be loose and rather frequent but otherwise not very abnormal, such an interval being followed by an exacerbation of the diarrhœa and repetition of the passage of blood and mucus. This type of trouble may persist for years if established ulceration of the colon fails to heal under appropriate treatment by emetine, serum, bowel wash-outs, or perhaps by surgical measures such as appendicostomy, colostomy, carcostomy, or colectomy. The diagnosis is based partly on the history, especially of residence in the tropics, partly on what is seen through the sigmoidoscope, partly upon the results of microscopical and bacteriological examinations of the stools, and partly upon serum agglutination tests.

Amœbic dysentery in its chronic form is diagnosed chiefly by three methods, namely : (a) Discovering the *Amœba histolytica* or its encysted forms in the stools ; (b) Seeing the characteristic ulcers with the sigmoidoscope ; (c) Finding that the condition is relieved or cured by the use of emetine, either as emetine hydrochloride given subcutaneously, or as bismuth-emetine-iodide given by the mouth. Should there be hepatic abscess as a complication, the bowel infection is or has probably been amœbic. There are no characteristic blood changes or serum reactions.

The *Amœba histolytica* is a large motile protoplasmic body with a relatively small nucleus ; each amœba may measure from 30 to 40 μ m. in diameter, and it is seen best when an emulsion of the stools is examined fresh under the low power of the microscope, a warmed stage being employed. It requires expert knowledge, however, to distinguish it from the harmless *Amœba coli* ; though if red corpuscles are seen to be engulfed in the amœba it is more likely to be *histolytica* than *coli*. The encysted forms are even more difficult to distinguish at sight than are the motile types. It assists the examination if a little methylene-blue solution is added to the faecal emulsion, for the stain is taken up by pus and epithelial cells at once and not by the living amœbæ, which stand out as light refractile motile bodies by contrast.

The sigmoidoscopic appearances of amœbic dysentery differ from those of bacillary dysentery and of ulcerative colitis, in that, instead of quite irregular and widespread ulceration, with general angry reddening of the mucosa that is not denuded by the ulcerative process, there are usually a number of relatively small separate well-defined ulcers with reddened margins and pitted bases ; once seen, these characteristic amœbic ulcers can often be recognized at once in subsequent cases, and the diagnosis may be based upon their appearances alone.

The therapeutic test by emetine applies only to amœbic dysentery ; the drug is of slight value in dysentery or in colitis due to other causes. Amœbic ulcers and other amœbic lesions may be cured completely by its use.

Bacillary dysentery is probably caused by a greater number of different bacilli than have yet been differentiated or discovered ; the best known organism causing the disease is *Shiga's bacillus*, which is doubtless the cause of most cases of dysentery coming from India, Egypt, Japan, China, and other Eastern countries ; it may also be the chief cause of dysentery in some epidemics in East, West, and Central Africa, the West Indies, Panama, and Central and South America ; but on the other hand it is quite possible that different bacilli, yet to be differentiated, may also cause dysentery in these places and elsewhere ; *Flexner's bacilli* may be specific, or, like the varieties of typhoid and paratyphoid bacilli, they may be but subvarieties of the main genus. These things we do not yet know ; but it is certain that though Shiga's bacilli may be typical in many cases of bacillary dysentery, there are many other cases of apparently similar dysentery in which the bacteriological findings reveal organisms which do not conform strictly to the Shiga type. Though the cases are grouped together as instances of 'bacillary dysentery,' the fact that the causal

bacilli are not necessarily identical in different cases and in different countries has three important bearings upon diagnosis : (a) The bacteriological findings in the stools may leave one in doubt as to whether they prove that the case is bacillary dysentery or not : (b) Whereas in typical cases the patient's blood-serum gives a positive agglutination with cultures of Shiga's bacilli, and thus helps to establish the diagnosis, the absence of such agglutination test does not prove the contrary, any more than a negative Widal's serum test to typhoid fever proves that a patient, suffering clinically from enterica, is not infected by paratyphoid A or paratyphoid B : (c) Whereas certain cases of bacillary dysentery may be cured, almost as by a specific, by the use of Flexner's or other antidyenteric serum given subcutaneously, intravenously, or by the bowel, other cases are not helped much by the serum treatment, and yet the fact that they are not helped does not exclude their being bacillary cases.

When, however, a case is pretty surely tropical dysentery, and no amœbæ are found in the stools, and the sigmoidoscope reveals, not the discrete punched-out disseminated ulcers of the amœbic disease, but a more diffused, irregular, angrier ulceration of the colonic mucosa, the diagnosis of bacillary dysentery becomes highly probable even though the stool-cultures are indeterminate and the patient's blood-serum does not give a positive reaction with Shiga's or Flexner's bacilli cultures.

Ulcerative colitis presents appearances, symptoms, and prognosis very similar to those of persistent bacillary dysentery. The chief point of distinction is geographical. The malady may extend over years, with remissions : but unless treatment by antiseptic enemata or by surgical measures is fortunately successful, the patient generally becomes reduced to a progressively lower level by each exacerbation, and dies of the bowel disease and its effects, one of which may be the development of progressive anemia simulating pernicious anemia, another the development of lardaceous disease. Frequent action of the bowels, accompanied by local or general abdominal pain of a colicky nature, by tenesmus, and often by the passage of abundant mucus and variable amounts of blood per rectum, constitute the chief symptoms. So-called mucous colitis is quite a different disease. There are no ulcers to be seen in the bowel in the latter, but in ulcerative colitis the sigmoidoscope reveals an angry, blood-oozing mucosa with irregular diffuse ulceration similar to that seen in bacillary dysentery. The history and the look of the stools and the sigmoidoscopic appearances give the diagnosis : there is no positive serum test that is generally applicable, and the therapeutic tests by emetine or by antidyenteric serum do not apply. Many cases doubtless have a microbial causation, and the condition may be epidemic, as in *asylum dysentery* : but the bacteriology of ulcerative colitis as distinct from tropical dysentery is far from clear. Some cases may result from the overuse of purgative drugs, notably calomel : others follow severe microbial illness elsewhere, and may be pneumococcal after pneumonia, streptococcal after erysipelas, and so on, but this is not certain : a severe form is met with in the late stages of chronic tubal nephritis, where it may perhaps be the result of excretion into the bowel of protein products that irritate,

irritate, and destroy the unaccustomed bowel mucosa. Some cases may represent changes in the bowel mucosa allied to eczema in the skin, for certain skin diseases, notably pemphigus and allied bullous dermatoses, may be associated with ulcerative colitis in a way which suggests that whatever causes the skin trouble is also the cause of the colitis and its ulceration. When one has diagnosed ulcerative colitis one has only advanced one stage : it is still beyond us, as a rule, to assign the ulcerative colitis to its precise cause in individual cases.

Syphilitic proctitis is much rarer than of yore : few cases are seen now. The condition is chronic, and although it may trouble the patient to some extent by reason of the diarrhœa and tenesmus it produces, and by the blood and mucus that may be passed, it may, on the other hand, lead to surprisingly little inconvenience until, in the process of the healing of the ulcers, stenosing of the rectum is brought about. Then severe and increasing constipation is far more trouble than was the previous diarrhœa. The ulceration may simulate carcinoma of the rectum, but is distinguished by the facts that it starts immediately above the anus, whereas carcinoma generally leaves a belt of unaffected mucosa between the anal ring and the growth : that it is different in appearance when seen with the proctoscope ; that it lasts longer than carcinoma does ; and that it tends to heal, especially under the influence of mercury, iodide, and salvarsan. It is distinguished from

ulcerative colitis by the fact that the upper margin of the ulcerated area is limited, the ulcers seldom extending more than six inches upwards, generally less, the mucosa higher than this being perfectly normal.

Tuberculous ulceration of the rectum is uncommon—far rarer than similar ulceration of the ileum and caecum. When it does occur it may simulate carcinoma, or venereal ulceration, or ulcerative colitis; the fact, however, that the character of the ulceration as seen through the proctoscope or the sigmoidoscope is peculiar, and not typical of other forms, will lead to swabbings from the ulcers being taken, when tubercle bacilli will generally be found in the films made from them; or tuberculous trouble may be discovered in the lungs or elsewhere to give the clue. Tuberculous ulceration of the rectum, unlike dysentery, ulcerative colitis, or syphilitic proctitis, tends to affect and destroy the anal mucosa by direct extension, and to invade the adjacent skin to a degree which may at once suggest the diagnosis.

The Passage of Blood per Anum in a Child. This calls for special comment. Soon after birth an infant may temporarily pass bright blood with the stools without the cause being more serious than *septic infection of the umbilical cord*: the amount of blood passed is but small, and the condition transient as a rule. A much more serious condition is *melæna neonatorum*, discussed on p. 481.

When the infant is a few months old, especially about the age of eight or nine months, *acute intussusception* is a condition to be suspected if blood, with or without mucus, is passed per anum. The infant will indicate that it is in pain by screaming and drawing up its legs; there will be vomiting; and after an initial evacuation of the normal contents of the lower bowel no true faeces will be passed, the diapers becoming reddened by the bloody mucus that passes in small amounts at intervals. There is no time for delay if the infant's life is to be saved by operation: a palpable abdominal lump is to be felt for, if need be under an anæsthetic. Although the intussusception starts at or near the ileocecal valve, as a rule the right iliac fossa is the least likely place for the lump to be felt in, for as the invagination of the bowel progresses the hardened distal end of the intussusception travels along the colon so that it may be felt under the liver, in the epigastrium, or on the left side of the abdomen; it may even be felt by a finger inserted gently into the rectum. For some reason acute intussusception is commoner at about nine months old than at any other time, and therefore the passage of blood and mucus by an infant of this age merits the most careful attention. At later ages intussusception is much less likely, and when the condition occurs in an adult it is usually not acute but subacute or chronic, leading to abdominal pains, constipation which may not be absolute, associated with a state of affairs which leads to laparotomy, the precise diagnosis being made as a rule only after the abdomen has been opened.

When the child is a year or two old *prolapse of the anal mucosa* may be the cause of passage of blood per anum. It is a fairly common condition, due apparently to the effects of straining at stool when the child is left too long continuously sitting on the chamber. It is associated with constipation but not necessarily with ill health: it is recognized by inspection. The prolapse may not be obvious by the time the child is brought to the doctor, but the mother recognizes it, and is alarmed by the globular red swelling which she sees projecting from the anus when she takes the child up from the chamber. Adults may develop a similar condition in association with piles and constipation, necessitating a troublesome process of 'pushing the bowel back' after each evacuation.

Alarm lest intussusception may have occurred may arise when older children pass blood per rectum in association with *acute zymotic diarrhæa*, especially common in summer time. Doubtless many of these cases develop acute enterocolitis with blood-oozing from the inflamed mucosa; but the condition does not lead to ulceration. Vomiting may be as marked as the diarrhæa: there may be cramp-like attacks of abdominal colic and pouring diarrhæa, the motions often assuming a grass-green colour. The diarrhæa and vomiting may be very serious, often fatal, but the occurrence of blood per anum does not make the prognosis worse. The abdomen will be examined for the possible tumour of an intussusception, but the fact that faecal material is passed, even though in small quantities only after the first few evacuations, will suggest that enterocolitis and not intussusception is the diagnosis.

Henoch's purpura is a striking malady, the nature of which may be obscure in the

first attack ; when, however, the child has recurrences from time to time as the years go by the diagnosis becomes easy, and the trouble generally ceases before adult life is reached. It seldom kills. In a typical attack the little patient is seized, when previously in good health, with a prostrating illness associated with pyrexia, vomiting, abdominal pains now here, now there, and sometimes diarrhoea, sometimes constipation ; very soon purpuric

Fig. 96. Ova of *Bilharzia hematobia*, with red corpuscles, from centrifugized urine. (High power.)

spots develop in the skin, recurring in successive crops, and possibly affecting all parts of the limbs and trunk (Fig. 337, p. 428). A severe case might be described as a combination of cyclical vomiting with generalized purpura. The attack may last a week or weeks, passing off gradually ; good health may be maintained for a variable interval ; then there is a recurrence of precisely similar symptoms ; and during the years between 5 and 15 the patient may have anything between two or three and a dozen or more bouts, ultimately ceasing to be subject to them. Many of the cases exhibit no more than the purpura associated with the gastro-intestinal upsets, but a few go further and present other hæmorrhages besides purpura—epistaxis, hæmatemesis, hæmoptysis, hæmaturia, melæna, blood per anum. The latter is never a solitary symptom, however, and the diagnosis depends not on it but upon the other phenomena of the disease. Sometimes there is extensive hæmorrhage into the submucosa of the bowel, with violent abdominal pains comparable with those of mesenteric embolism or of intussusception ; indeed, the cessation of peristalsis in a short length of bowel affected by submucosal hæmorrhage may cause the active bowel above to drive the hæmorrhagic part by invagination into the part below and produce an actual intussusception as a complication of what is primarily Henoch's purpura. Such violence of the malady is fortunately rare, but it needs to be borne in mind as a possibility in cases in which the passage of blood per rectum in association with absolute constipation has become a pronounced feature of the attack.

There remain for discussion two other groups of causes for the passage of blood per anum, both rare but both important, namely : (1) *Parasites*, especially *Bilharzia hematobia*, *Oxyuris vermicularis*, *Ankylostomum duodenale* ; and (2) *Gastro-intestinal irritant drugs*—chemicals, especially calomel and arsenic.

1. Parasites.—*Bilharzia hematobia*, known also and more correctly as the *Schistosoma hematobium*, may occur in the rectum, though less frequently here than in the bladder. Its presence gives rise to the passage of mucus and blood per anum. There may be discomfort in the rectum and frequency of defæcation. Infection is contracted abroad, especially in Egypt—a fact which may lead to a suspicion of the presence of the affection in patients who have resided out of England. Diagnosis depends on finding the ova of the parasite in the faeces or in the urine. Their well-known shape—oval with a pointed spike at one end (Fig. 96), or rarely at the side—renders them unmistakable under the microscope.

In children the presence of thread-worms (*Oxyuris vermicularis*) in the rectum may lead to the discharge of small amounts of mucus coloured by a trace of blood. The worms will be seen readily on inspection of the child's motions. They are white, about as thick as coarse thread, and $\frac{1}{2}$ to $\frac{3}{4}$ in. long.

Fig. 97. *Ankylostomum duodenale*. A, Head with hooks ; B, Tail ; C, Entire worm. (Low power.) (From Medical Laboratory Methods, by French and Nuttall.)

Infection by *Ankylostomum duodenale* (Figs. 97-99) — ankylostomiasis — is characterized by pronounced anaemia simulating pernicious anaemia, associated with asthenia without obvious cause; though patients may harbour ankylostomes without exhibiting any symptoms at all. Blood occurs in the stools, but it is seldom obvious; generally it is detected by the tests for occult blood given below. Blood-counts in bad cases may exhibit most of the characters exhibited by those of patients with pernicious anaemia, even to the occurrence of a high colour index, but with this very important difference, namely, that Eosinophilia (p. 271) is often marked in ankylostomiasis cases and is very rare in pernicious anaemia. Eosinophilia in a case of supposed pernicious anaemia should always lead to a search for evidence of parasitic infection, especially by tape-worm, ankylostome, or bilharzia. Ankylostomiasis may be suggested by former residence abroad, particularly in Egypt, South Africa, South America, Mexico, India, Assam, or Siam, though cases occur in European countries to which the infection has been introduced from overseas — for instance, in the Cornish lead mine epidemic and in the St. Gothard tunnel workers; the diagnosis is established by detection of the parasites or their ova in the stools, notably after the administration of an anthelmintic such as thymol or carbon tetrachloride, the latter in 20-minim doses being almost a specific for the cure of the disease.

2. Gastro-intestinal Irritants of a chemical nature are numerous, but the majority cause blood per anum only when administered for suicidal or homicidal purposes for instance, sulphuric acid, nitric acid, hydrochloric acid, corrosive sublimate — the diagnosis then depending upon the collateral evidence in the case. Two, however, that may cause blood per anum, sometimes even when the dose has been within therapeutic limits, are *arsenic* and *calomel*.

Arsenic is well known as liable to upset digestion when used in the treatment of chorea, pernicious anaemia, certain skin diseases, and so forth; sometimes it has been administered with felonious intent by murderers in the form of weed-killer, the symptoms produced in the patient being attributed to gastric ulcer or to ulcerative colitis; in either case the diarrhoea may be accompanied by the passage of blood and mucus in the stools; epigastric pain and tenderness, vomiting, rapid irregular pulse, clammy cold sweats, and recurrent bouts of collapse may be prominent features of the case, the nature of which may baffle diagnosis unless there is knowledge that arsenic is being taken, or unless analyses of the vomit or of the stools lead to the detection of arsenic by Reinsch's or Marsh's test.

Calomel is usually a harmless purge, but sometimes, particularly in cases that are already septic, it leads to definite and even fatal colitis; when the latter is extreme bloody mucus is passed per rectum, and not a few cases of fatal ulcerative colitis have been started by the giving of calomel in doses that would ordinarily be regarded as within therapeutic limits. The diagnosis depends upon knowledge of the administration of the drug.

II. BLACK BLOOD IN THE STOOLS.

For this condition see MELENA, p. 481.

III. OCCULT BLOOD IN THE STOOLS.

Most of the conditions described above may sometimes lead to the passage of so little blood in the stools that it is not obvious unless special tests are applied to the motions for its detection—under which circumstances the state of affairs is labelled ‘occult blood in the stools’. Nevertheless, the occurrence of such occult blood merits special discussion because it may be of particular importance, notably in our attempts to decide whether there is activity in connection with a gastric ulcer, a duodenal ulcer, or a gastric carcinoma.

It will be important, of course, to exclude lesions of the colon, such as colitis or new growth, by sigmoidoscopy, X-ray examination, a careful scrutiny of the history; parasitic infection by examining the stools for ova or worms, and the blood for eosinophilia; and so on; but when it has become a question as to whether the patient may have merely visceroptosis, hyperchlorhydria, functional dyspepsia, on the one hand, or an ulcer of the stomach or duodenum on the other, examination of the stools for occult blood may be an important factor in the differential diagnosis. It is essential to exclude foods containing hæmoglobin or chlorophyll before the tests can be relied on; and the following routine, though it may appear elaborate, is wise before the tests are applied. First, the diet should be restricted for the time being to items that contain no green vegetables, and no meat or meat products, even gravy soups, beef tea, and bovril being excluded; secondly, steps should be taken to see that the stool examined dates from a time that is certainly subsequent to the last partaking of meat products or greens. After the special diet has been started one should wait until the next stool has been passed; then two teaspoonfuls of powdered charcoal should be taken three times in the day for one day, and the subsequent stools should be observed until those containing the charcoal have been seen; then, the special diet being continued, the next stool subsequent to the last one containing charcoal should be the first one taken to be tested for occult blood. If occult blood is then definitely present the probability is that the patient has definite ulceration of the stomach or duodenum, if upon other grounds the diagnosis has been narrowed down to being either this or a less serious one of simple indigestion. With these provisos, the occurrence of occult blood in the stools has very real diagnostic significance.

Testing for Occult Blood.—The methods employed for the detection of occult blood in the motions are various; in some cases it may suffice to place a smear of the stool upon a piece of lint, drop a few drops of tincture of guaiacum over the stool smear, and then pour a few drops of fresh ozonic ether over the whole, the occurrence of a bright blue stain at the margins of the mixed ingredients on the lint being definite evidence that blood derivatives are present. More often it is essential to use more delicate methods, and to extract any blood pigments that may be present by the following procedure: A portion of the stool, about the size of a large pea, is rubbed up into an emulsion with a small amount of water, preferably distilled; a glass rod in a test-tube is convenient for doing this; one may then apply either: (1) The spectroscopic test; (2) The guaiacum test; or (3) The benzidine test.

1, 2. *The Spectroscopic Test and the Guaiacum Test.* These may be taken together. A convenient amount of the emulsified stool one adds half as much glacial acetic acid, and as much pure ether as acetic acid; the mixture is shaken well, and reshaken several times; it is then allowed to stand until the ether separates from the water as an upper layer which can then be decanted into a fresh, clean test-tube. The ethereal solution may be divided into two parts. The first is examined spectroscopically for the bands of either oxyhæmoglobin (*Fig. 17*, p. 13) or acid hæmatin (*Fig. 21*, p. 13), indicative of blood or its derivatives; the second is tested by the addition of a drop of fresh tincture of guaiacum followed by several drops of either ozonic ether or of a 3 per cent solution of hydrogen peroxide, the development of a greenish-blue or of a definite blue colour indicating that blood derivatives are present.

3. *The Benzidine Test.*—The emulsion of stool is first boiled in its test-tube and then cooled; an equal amount of saturated solution of benzidine in glacial acetic acid is added; the mixture is shaken up, and a 3 per cent solution of peroxide of hydrogen is added drop by drop, watch being kept for the development of a greenish-blue tint if minute quantities of blood are present, or of a decided blue hue as evidence of definite occult blood.

Herbert French.

BLOOD, VOMITING OF. (See HÆMATEMESIS, p. 336.)

BLOOD-PRESSURE, ABNORMAL.—Blood-pressure cannot be gauged accurately with the finger, but is determined by one or other of the many forms of sphygmomanometer now in general use. The *maximum systolic arterial pressure* is the easiest to measure; it is given by the reading of the manometer when the pulsations of the radial artery just cease to be perceptible to the palpating finger at the wrist. Measurement of the *minimum diastolic arterial pressure* is made less readily by the palpation method than it is by auscultating the brachial artery with the stethoscope at the bend of the elbow whilst the pressure in the bag is raised steadily by the hand-pump; a certain amount of practice is required in using this method. When the sound of the blood-flow ceases, the reading of the manometer gives the maximum systolic pressure; when the air is now let gently out from the bag, the sound begins to be audible as the blood-flow through the artery returns, and it increases in loudness up to a maximum; a reading of the manometer taken at the time the sound has just reached this maximum gives what is considered to be the diastolic pressure.

The difference between the systolic and the diastolic pressures is termed the *pulse-pressure*; and the average between the systolic and the diastolic pressures is termed the *mean arterial pressure*.

It does not follow that if the systolic pressure is high the diastolic is also high, though it may be. In a case of aortic regurgitation, for example, the systolic pressure may be 160 mm. Hg, the diastolic 70 mm. Hg, giving a pulse-pressure of 90 mm. Hg, but a mean pressure of 115 mm. Hg; in a case of arteriosclerosis the systolic pressure may be 210 mm., the diastolic 190 mm. Hg, the pulse-pressure being then 20 mm. Hg and the mean pressure 200 mm. Hg. There is no constant relationship between systolic and diastolic pressures even in health, but an average in anyone under thirty years of age would be about 120 mm. Hg systolic pressure, with a diastolic of about 90. Prolongation of the first sound at the impulse, or a ringing accentuation of the aortic second sound, may serve to indicate that there is a high blood-pressure when no instrument is at hand to verify the fact.

There is a great deal to be learned still about the clinical significance of diastolic pressures and pulse-pressure; from a practical point of view, what we know most about is the importance of the maximum systolic pressure. This may be *abnormally low* or *abnormally high*, but no stress should be put upon any but considerable departures from the normal. Healthy individuals who have not been kept in bed have an average pressure in early adult life of 120 to 130 mm. Hg. Children have less than this, though at this early age it seldom happens that anything is to be learned by measuring the blood-pressure. As years advance, the blood-pressure tends normally to rise, so that at fifty or sixty a reading of 150 or 160 mm. Hg, or thereabouts, which in a younger person might indicate disease, may be normal, and it is a rough-and-ready rule to allow a patient a systolic blood-pressure indicated by putting 1 before his age without calling a reading less than this abnormal.

Abnormally high blood-pressure may reach figures such as 320 mm. Hg, and anything from 170 mm. Hg upwards is essentially abnormal, whatever the age of the patient. A patient who is kept in bed tends to have a diminution in the blood-pressure, and this applies to arteriosclerotic patients as well as others; a person may have a blood-pressure of 250 mm. Hg or more when up and about, and yet when he is kept in bed the pressure may fall to 150 mm. Hg, to rise again when he returns to active life.

There are various conditions which cause raised blood-pressure, some fairly well understood, some quite obscure; at one time it was thought that the finding of a systolic pressure of 180 mm. Hg or over was necessarily a point of grave omen, but more experience has shown that many such cases live long without necessarily suffering from any symptoms at all; lives have been spoiled by restrictions imposed without intrinsic benefit or need, and all the other circumstances of each case should be taken into full account before hyperpiesis (high blood-pressure) is interpreted as indicative of a state of affairs which is to be labelled really serious. On the other hand, it is always difficult to say that the existence of a high pressure does not indicate the insidious onset of arterial or renal disease; and for this reason it is of much importance in connection with life insurance: most companies

require measurement of the blood-pressure as part of the routine medical examination now, and they are chary of accepting lives if the systolic pressure is above the normal maximum for the age.

The two main serious conditions causing high systolic blood-pressure are : (1) *Arteriosclerosis* ; and (2) *Chronic nephritis* ; and the three chief dangers are : (1) cerebral hæmorrhage ; (2) failure of cardiac compensation ; and (3) impairment of sight from albuminuric retinitis, retinal hæmorrhage, or hæmorrhage into the vitreous. Quite a number of cases first come under observation as the result of seeing an ophthalmic surgeon for sight troubles ; the tortuous or thin wiry appearance of the retinal arteries may suggest the nature of the trouble. On the other hand, the patient may have seemed to be in perfect health until stricken suddenly by an apoplexy ; or he may have been short of breath on exertion, fearing a cardiac lesion for which he sees the doctor ; or, again, he may have had no symptoms whatever, the high blood-pressure being discovered solely as the result of a routine medical examination. Pressures as high as 320 mm. Hg are met with occasionally, but these are very uncommon, and anything over 200 mm. Hg, if persistent, is a sign of dangers ahead. There are, however, patients in whom the blood-pressure varies so much on different days, or at different times on the same day, that it is extremely difficult to determine what the precise significance of some of the higher readings may be ; they may vary from 220 mm. Hg to 150 mm. Hg within a few hours ; we have yet to learn what the various chemical, nervous, endocrine, emotional, and fatigue factors are that may be responsible for this sort of condition, and the course of the case will sometimes prove that arteriosclerosis or renal degeneration, suggested when the high reading is first found, are not responsible. In some such cases treatment by small doses of thyroid extract will help the patient much, but even when this is so it is uncertain whether one can attribute the occasional hyperpiesis to hypothyroidism. The difficulties of interpreting the significance of the occasional high readings in some such cases, particularly in women of middle age, are at present still beyond our powers of solution. It is noteworthy that some cases of *acromegaly* present remarkably high blood-pressure at times, the readings varying greatly even in the course of a single day ; the figure may be 300 mm. Hg at one time, 160 mm. Hg at another time a few hours later, and the variation takes place without any evidence of it on the patient's part. Pituitary vagaries may be responsible for analogous variations in individuals who are not clinically acromegalic.

Contrary to what might be expected, the maximum systolic blood-pressure is often higher than normal in cases of heart failure such as result from *mitral stenosis*, even when the pulse is so irregular and feeble that it can only be felt with certain beats, and when one would have thought that there must be a fall in the blood-pressure ; the cause for the rise in such cases is probably the *partial asphyxia* acting upon the vasomotor centre ; similarly, a rise of blood-pressure, even to 220 mm. Hg or more, may accompany the asphyxial attacks of Raynaud's syndrome. Cases of *melancholia* have abnormally high blood-pressures ; when the melancholia improves, the pressure falls, and may return to normal when the patient recovers from the mental symptoms. The chief importance of high blood-pressure is, however, in diagnosing arterial or renal degeneration, with consequent tendency to *apoplexy* or to *chronic heart failure*.

Abnormally low blood-pressure of moderate degree may be observed in many different circumstances associated with *asthenia* ; it is not uncommon in those who have resided long in India or other tropical lands ; in those who have some debilitating malady—in phthisis, for instance, it may often be below 100 ; it is apt to accompany *Graves' disease* ; and *excessive smoking*, particularly of *cigarettes* ; but in itself a low maximum systolic blood-pressure is seldom of diagnostic significance excepting in *Addison's disease*. In a case in which the degree of pigmentation of the skin or of mucous membranes may leave doubt as to whether Addison's disease is the diagnosis or not, a blood-pressure so low as 80 or 70 mm. Hg would be confirmative of the diagnosis, although there are cases of Addison's disease in which the blood-pressure may be no lower than 120 mm. Hg.

Herbert French.

BLUE SCLEROTICS.—(See FRACTURE, SPONTANEOUS, p. 304.)

BLUE-BRAIN. (See DEAD FINGERS, p. 203.)

BOILS.—(See PUSTULES, p. 681.)

BONE, SWELLING ON A. (See SWELLING ON A BONE, p. 817.)

BONES, SPONTANEOUS FRACTURE OF.— (See FRACTURE, SPONTANEOUS, p. 304.)

BORBORYGMI are gurgling noises in the abdomen produced by peristaltic movements of the bowel acting upon the mixed gaseous and fluid contents. With the stethoscope applied to the abdomen they may be heard in all normal persons, varying in intensity at different phases of digestion. When a meal has been taken after a period of fasting, the passage of the intestinal contents through the ileocecal valve may be heard distinctly with the stethoscope placed over the right iliac fossa some six hours or less after the meal; but it is seldom possible to decide what precise portion of the bowel is responsible for the production of borborygmi heard elsewhere.

Normally, these sounds should not be audible either to the patient or to other persons; but occasionally even in health they may be heard quite loudly, becoming even annoyingly obtrusive in some individuals who may nevertheless be in perfect health apart from liability to various purely functional disorders. The sounds are apt to be loudest when the alimentary canal is relatively empty: for instance, when a meal is overdue; or when the patient, often a functionally nervous woman, eats inadequately at meal-times, or when a person is beginning to get over-hungry. They may be associated with flatulence and either constipation or diarrhoea, though by no means necessarily so. Fermentation of carbohydrates is suggested when the borborygmi are increased by carbohydrate foods. Less frequently they result from chronic inflammation of the bowel, in association, for example, with the after-effects of dysentery or with ulcerative colitis; or they may be due to the powerful peristaltic waves of a bowel that is hypertrophied above a constriction caused by a band or a carcinoma of the colon. The sigmoidoscope, bacteriological examination of the stools, or X-ray examinations after a bismuth meal or enema may be required in cases of doubt: pronounced borborygmi are more often due to functional disorder than to organic disease.

Borborygmi are apt to be increased in asphyxial conditions, and may be very marked in cases of heart failure with cyanosis.

The absence of borborygmi may sometimes be important, for one of the first effects of peritonitis is to inhibit peristalsis: without peristalsis borborygmi cannot be produced, and therefore, if peritonitis is suspected, the presence of well-marked borborygmi on auscultation of the abdomen is an argument against there being general peritonitis, whilst complete silence of the abdomen is in favour of this diagnosis.

Herbert French.

BRADYCARDIA, or undue slowness of the pulse-rate, is compatible with health, some individuals having a normal pulse-rate of 50, whilst in a few it does not exceed 40 or even 30 per minute (*Fig. 100*). Occasionally bradycardia of this kind is found in more

Fig. 100. Electrocardiogram from a patient who was free from heart disease but exhibited persistent bradycardia, with a pulse rate of about 10 beats per minute without heart-block. Time markings in $\frac{1}{4}$ and $\frac{1}{2}$ sec.

than one member of the family. It is important to auscultate the heart to exclude the possibility of the rate of the pulse as felt at the wrist not being the same as the rate

of the heart-beat: often, particularly with mitral stenosis, by no means every pulse-wave becomes palpable at the wrist, and the rate may then seem to be slow when perhaps in reality the heart-rate is very fast.

Fig. 101. Electrocardiogram showing complete heart-block. The auricular waves (P) occur at regular intervals, but bear no relationship to the ventricular waves. At X the auricular and the ventricular waves are simultaneous. Time markings in $\frac{1}{2}$ and $\frac{1}{4}$ sec.

Fig. 102. Electrocardiogram to illustrate one-in-two heart block. It will be noticed that the auricles and ventricles are both beating perfectly regularly, but the auricle notches (P) are twice as numerous as the ventricle notches (R). Only every second auricular beat was followed by a ventricular beat. The illustration is from the same patient as *Fig. 101*, but upon a different occasion. He sometimes exhibited partial heart block as above, and sometimes complete, as in *Fig. 101*.

Absolute slowness of the pulse-beat, as distinct from its relative slowness in proportion to pyrexia, is best seen in the symptom-complex termed *Stokes-Adams' disease*, the

phenomena of which are syncopal attacks associated with epileptiform convulsions, coma, stertor, and cyanosis, the rate of the heart-beat being found to have dropped to half or even to less than half of that which is natural to the patient. The underlying cause is difficulty in the transmission of the contraction-stimulus from auricle to ventricle along the auriculo-ventricular bundle of His. The inhibitory factor is not the same in all cases, and sometimes it is a transient effect of the action of microbial toxins during fevers, passing off as the cardiac musculature recovers from the cloudy swelling or other changes that the febrile illness has caused; but is often associated with graver degenerative changes in the bundle of His, together with arteriosclerosis, myocardial degeneration, and atheroma, or to the effects of syphilis of the bundle of His, or to destruction of that bundle by a gumma, sarcoma, or carcinoma. The phenomena of Stokes-Adams' disease do not result when the heart-block is complete as in *Fig. 101*, where the patient's ventricles were beating at their own constant rate quite independently of the auricles; but rather when the block is of less degree, so that at times most of the auricular beats pass on to the ventricles but at other times fewer get through; it is when the sudden change from many beats to few beats occurs that the epileptiform phenomena of Stokes-Adams' disease are most pronounced. The diagnosis is apt to be that of epilepsy until the fact has been established that the pulse-rate falls during an attack to about half the normal; but when this observation has been made, the difference between Stokes-Adams' disease and ordinary epilepsy is clear. The phenomena are those of 'heart-block', the diagnosis of which in its lesser degrees cannot be made without careful instrumental records of the venous and arterial pulses and of the cardiac movements, made either by means of the polygraph, or better still the electrocardiograph (*Figs. 101, 102, 104*). The first indication

Fig. 101. Portion of an electrocardiogram showing a normal P-R interval. The auricular wave P, the ventricular wave QRS, and the T wave are marked from the A.C. tracing, which is the tracing of the heart.

Fig. 104. Portion of an electrocardiogram showing a prolonged P-R interval. The auricular wave P, the ventricular wave QRS, and the T wave are marked from the A.C. tracing, which is the tracing of the heart. The time-intervals are in the 1/2 second.

in an electrocardiogram that there is partial heart-block is an increase in the distance between the auricular wave P and the ventricular wave R. This P-R interval should not exceed $\frac{1}{2}$ second in health; when it is longer, as in *Fig. 104*, it affords evidence of defective conduction from auricle to ventricle and therefore of impending heart-block.

Considerable slowing of the pulse-rate has also been noted in some cases of *uræmia*, even without heart-block; both in the chronic type of the affection and during uræmic coma. Bradycardia is by no means constant in uræmia however.

Increased intracranial pressure sometimes causes bradycardia in cases of *cerebral hæmorrhage, tumour, or abscess*, and in the early stages of *tuberculous meningitis*; in other forms of meningitis, and in the later stages of tuberculous meningitis, the initial bradycardia changes to tachycardia. If in a given case there is otitis media or some other local infective focus which might produce a cerebral abscess, pyrexia with a pulse-rate of 50, 55, or 60 is an argument in favour of intracranial abscess; the other complications of otitis media, especially lateral sinus thrombosis, mastoid abscess, or suppurative meningitis, produce a rapid pulse-rate instead of a slow one; the reverse is not true, for it is not possible to exclude cerebral abscess merely on the ground that there is no bradycardia. Cerebral tumour can generally be distinguished from cerebral abscess by the greater length of the history, the more pronounced optic neuritis, or the absence of predisposing cause to cerebral abscess, such as otitis media or bronchiectasis; whilst cerebral hæmorrhage is more rapid in its onset, is less likely to have marked optic neuritis, and if there is pyrexia it is apt to be extreme, reaching the level of hyperpyrexia; generally the patient is an elderly man who has either high blood-pressure, albuminuria, or other evidence of degenerated arteries or granular kidneys.

In *myxædema* the pulse-rate is seldom fast, and it may be abnormally slow.

Certain drugs are apt to slow the heart markedly when they have been administered in full doses over a long period, the three most important being *digitalis*, *strophanthus*, and *sodium salicylate*; the diagnosis depends on knowledge of the medicine the patient is taking.

Jaundice is generally stated to cause marked slowing of the pulse-rate: it is true that artificial introduction of bile salts and pigments into the circulation in animals slows the heart, but clinically in man it is rare to find jaundice and absolute bradycardia associated.

The Eastern malady *phlebotomous fever* may be accompanied or followed by extreme bradycardia.

Partial starvation extended over a long period, or the long-continued effort to live on inadequate forms of food, leads to the various phenomena of what has been termed 'exhaustion disease' or 'war oedema,' in which it is common to find a pulse-rate of 40 to 48 in association with polyuria, a tendency to general swelling or actual oedema simulating that of acute nephritis but without albuminuria, anaemia, poikilocytosis, anisocytosis, and a liability towards the end to ascites or pleural and pericardial effusions. The bradycardia may precede the other symptoms by weeks. Herbert French.

BRADYPNŒA, or undue slowness of breathing, is not a very common symptom, but it may be met with in marked degree under various conditions, of which the following groups are the chief:—

1. As an Effect of certain Drugs or Poisons :

Chloroform	Chloral	Sulphonal	Aconite
Opium	Chloral hydrate	Trional	Antimony.
Morphia	Butyl chloral hydrate	Tetronal	
Alcohol	Veronal	Medinal	

2. Cerebral Compression resulting from :

Depressed fracture of the skull	Pontine hæmorrhage	Cerebellar abscess
Meningeal hæmorrhage	Cerebral tumour	Osteoma of the cranium
Cerebral hæmorrhage	Cerebral abscess	Gumma of the meninges.
	Cerebellar tumour	

3. Shock or Collapse from :

Severe injury	Severe blood-loss, as from wounding,
Sudden onset of acute illness	hæmatemesis or hæmoptysis, or internal
Operations	bleeding from duodenal ulcer, rup-
Excessive loss of fluid from choleraic diarrhœa	tured ectopic gestation, or typhoid fever.

4. Caseous Bronchial Glands.

5. Functional Conditions :

Hysteria	Epilepsy	Catalepsy	Trance.
----------	----------	-----------	---------

6. Uræmia.

7. Diabetes Mellitus with impending Coma (' Air-hunger ').

Although bradypnœa may result from any of the above causes, it is not constant in most of them, and in the majority it is an incident which, even if present, is not of diagnostic importance. This applies particularly to the conditions mentioned in Groups 1 and 2, in many of which the patient is likely to be at least stuporous, and perhaps completely comatose (see COMA, p. 153). The *cerebral lesions* will be indicated by associated headache, vertigo and vomiting, and confirmed by the discovery of optic neuritis (*Figs.* 418, 419, p. 518).

Now and then, in the case of a child suffering from tuberculous meningitis, one comes across a curious type of slow breathing, in which two or perhaps three short respirations occur in quick succession, followed by so long a pause that the patient may appear to be dead. This type, known as Biot's breathing, does not resemble Cheyne-Stokes' breathing (p. 138) clinically, but it is probably related to it pathologically. It occurs in those who are approaching death, but may be present for a day or more before death actually occurs.

If the bradypnœa is due to a *poison*, the circumstances of the case may suggest this, and it may be confirmed by chemical analysis of the gastric contents or of the contents of adjacent bottles; though there may be the same difficulties of deciding whether the

patient is 'drunk or dying' as are discussed on p. 154. One important point is not to conclude forthwith that the presence of sugar in the urine indicates diabetic bradypnœa and coma, for numbers of patients suffering from deep alcoholism have sugar in their urine for the time being: generally, however, without acetone and in a low specific gravity urine.

In cases of *shock* or *collapse* the existence of bradypnœa will be overshadowed by the other symptoms in the case, and it is not in itself important.

The slow breathing that results sometimes from *caseous bronchial glands* differs from most of the above in that it affects patients, generally children, who are not acutely ill: though delicate, they may even be going to school, and yet their respiration-rate may be as slow as 12 or even 10 to the minute for weeks or months. There is generally tachycardia at the same time. Many such children shake off their delicacy in the course of a year or two, for the majority of cases with caseous bronchial glands get well without being diagnosed: the relationship between this bradypnœa and affection of the glands has been shown in patients dying from accidents. During life the diagnosis may be established by finding the shadow of the caseous glands in the thorax with the X rays (*Fig. 155*, p. 187).

Little need be said about the functional conditions in which bradypnœa may occur. *Old people* tend to breathe more slowly than young unless there is shortness of breath from emphysema, bronchitis, or myocardial affection. *Epileptics* breathe normally between their attacks: but during a seizure they cease breathing altogether for the first twenty seconds or so—the tonic stage—and then their respirations start slowly and stertorously: the bradypnœa may then cease suddenly, or it may persist in minor degree during the period of post-epileptic stupor. *Hysteria* may produce almost any symptom: bradypnœa is possible, though tachypnœa is more common: the diagnosis depends upon other features of the case (p. 570). *Catalepsy* and *trance* are both mental conditions, diagnosed by watching the case or by the history: in catalepsy the movements of respiration may be very slow, but they are obvious: in trance, on the other hand, the breathing movements may be apparently absent altogether for days or weeks, the patient lying motionless like one dead. The chief difficulty is to exclude actual death: the thermometer helps—the body does not become cold: the heart-sounds may be just audible even though the pulse cannot be felt: and the fact that some respiration is taking place may be recognized by holding a bright mirror close to the nostrils and mouth, when a slight dimming from condensation of expired air may be seen. In very exceptional cases, however, death is simulated so closely that the patient has been upon the verge of burial before the mistake has been discovered.

Uremia may be associated with breathing that is either rapid, or normal, or slow: the latter is exceptional: but in some cases of uræmic coma bradypnœa is pronounced. Cerebral compression by a hæmorrhage, abscess, or tumour may be simulated, and a knowledge that the urine contains albumin and tube casts, and that the blood-pressure is high, will not always decide between them. Recurrent convulsive seizures would point to uræmia to some extent, but they may also occur from gross brain lesions, and optic neuritis may also be common to both. To clinch the diagnosis of uræmia it may be necessary to test the blood or cerebrospinal fluid to see if it contains excess of urea.

Diabetes mellitus is liable to cause the most characteristic bradypnœa of all—the 'air-hunger' of diabetic coma. This is not a dyspnœa, as the name might suggest, but a condition of extremely deep slow breathing with a maximum respiratory excursion both in the intake and in the output of air. The 'hunger' for air is one of getting the maximum of air in and out with each deep slow breath, rather than one of getting in as many breaths as possible in a given time. The patient becomes increasingly drowsy, and generally complains of pains in the upper half of the abdomen. The breathing-rate begins to fall from 18 to 16, to 14, and progressively down to perhaps only 6 to the minute. There is a long pause between each breath, and then inspiration starts and, without any hurry, the stuporose patient goes on drawing air deeper and deeper into his chest until he cannot expand it to take in any more: the head is often thrown slowly back during the process, the mouth slowly opens wider and wider as the head goes back: then there is a pause at the height of inspiration before an equally deep, slow, solemn expiration follows, and the head comes forward and the mouth closes partially until the next slow

deep inspiration is in progress. The patient seldom lives much longer than forty-eight hours after this onset of air-hunger and diabetic coma, but the air-hunger is sometimes seen in cases not yet comatose. It may then pass off for a time, or may be relieved if insulin is given, but it is always a sign of grave danger, and it is the most characteristic of all the forms of bradypnœa.

BREAST, DISCHARGE FROM. (See DISCHARGE FROM THE NIPPLE, p. 227.)

BREAST, PAIN IN. (See PAIN IN THE BREAST, p. 529.)

BREAST, SWELLING OF. (See SWELLING, MAMMARY, p. 837.)

BREATH, FOULNESS OF THE. This is due to one or other of four main groups of conditions, namely: septic or putrefactive changes within the mouth, nose, or nasal sinuses; septic or putrefactive changes within the lungs; smoking or the ingestion of substances, such as garlic, onions, or paraldehyde, whose products are excreted by the lungs or saliva; severe toxic conditions, especially those affecting the alimentary canal or peritoneum.

When the foulness of the breath is not habitual, but occurs as the result of recent illness, there will be symptoms of the latter which point to the diagnosis quite apart from the condition of the breath, and one need merely indicate as possible causes such things as typhoid fever, general peritonitis, post-puerperal sepsis, intestinal obstruction, and a host of other conditions of this kind in which, even though the mouth be clean, there may be foulness of the breath, such tendency being greatly exaggerated if sordes have been allowed to collect.

Foulness of the breath due to the ingestion of foodstuffs such as *onions* or *garlic* is familiar enough; there are certain drugs, for instance *guaiacal* or *paraldehyde*, which may produce a similar symptom without the patient's friends realizing why the breath should be so tainted.

Foulness of the breath due to lung conditions will nearly always be indicated either by the abundant and putrid sputum, or by the abnormal physical signs in the thorax. The condition may be due to *phthisis* with secondary infection of the cavities by pyogenic organisms, *fatid bronchitis*, *bronchiectasis*, *gangrene of the lungs*, *empyema* (see Fig. 115, p. 132) or other *abscess* which has ruptured into the lung. The cases which give rise to most difficulty in differential diagnosis are those in which an empyema has been situated deeply, for instance between the lower lobe and the diaphragm, or between two lobes, without reaching the surface; there may be absolutely no abnormal physical signs, and the diagnosis has to be made from the symptoms and history. The patient has generally had some obscure febrile illness, possibly with cough, but without much expectoration, until one day, after a particularly severe bout of coughing, a large quantity of pus—perhaps a teacupful or more—has been brought up suddenly, since when, at intervals of hours and days, there

been similar expectoration of quantities of putrid pus. Deep-seated empyema without abnormal physical signs most resembles bronchiectasis or bronchiolectasis, but is distinguished by the sudden way in which the first large quantity of purulent expectoration came on. In both cases there may be clubbing of the fingers, the sputum contains pus-corpuscles and pyogenic and non-pyogenic micro-organisms other than tubercle bacilli, but no elastic fibres indicative of lung destruction. X-ray examination may reveal an abnormal shadow within one or other lung, corresponding to the deep-seated empyema.

Gangrene of the lung produces an unmistakable stench of the worst kind; the detection of elastic fibres in the sputum, after boiling with caustic soda to destroy other tissue elements, clinches the diagnosis.

Phthisis with cavitation may produce foulness of the sputum, but hardly ever the stench of gangrene, unless gangrene has supervened. It is distinguished from bronchiectasis and from hidden empyema by discovering tubercle bacilli in the sputum. The chief difficulty arises when the tuberculous part of the malady has ceased, the cavities formerly excavated by the tuberculous process having been usurped by secondary pyogenic organisms.

Foul breath is due in the great majority of cases to local decomposition in the mouth, often diagnosable on simple inspection in the form of *tarlar*, *septic gums*, *carious teeth* with decomposing food particles in them, *pyorrhœa alveolaris*, or *stomatitis*; or it may be that

the nose or throat is at fault rather than the mouth, as the result of *syphilis*, *necrosis of the nasal bones*, *purulent*, *hypertrophic*, *caseous*, or *atrophic rhinitis*, *chronic post-nasal catarrh*, *chronic pharyngitis*, *ozana*, *septic tonsillitis* or other varieties of SORE THROAT (p. 757), sepsis of the antrum of Highmore, frontal, ethmoidal, or sphenoidal sinuses; very vile foulness of the breath occurs with *Vincent's angina* (p. 760), and with *squamous-celled carcinoma* of the mouth, tongue, pharynx, tonsil, œsophagus, or larynx, with *endothelioma* of the antrum, or with a sloughing *fibrosarcoma* of the nasopharynx; in children the possibility of some *foreign body* having got impacted in the throat, nose, or nasopharynx should not be forgotten.

It is only when all such local conditions have been excluded, and when there is no acute illness or any lesion of the lungs, that one can attribute foulness of the breath to *constipation* or to *dyspepsia*. It is sometimes very difficult to find out why the patient's breath is not sweet, and indeed there are some persons in whom all the functions of the body seem to be normal, and the mouth clean, and yet the breath is foul. If there are any symptoms of gastro-intestinal disorder, especially flatulence or constipation, one is inclined to attribute the condition of the breath to the stomach or the bowels; but when there are no symptoms of error in these, it is more than likely that the trouble is due to some condition not discovered on ordinary inspection, particularly putrefaction of food particles which may become impacted between the teeth even in persons who use both tooth-brush and mouth-wash daily. X-ray examination of the teeth may be required before one can exclude periodontal or apical infections of one or more of these, particularly perhaps in association with old crowns which may superficially appear clean and sweet.

Herbert French.

BREATH, SHORTNESS OF. It is difficult to define precisely what should be implied by the term 'shortness of breath', for it has many degrees—from the temporary panting produced by a brisk run to the extreme dyspnoea of a patient suffering from mitral stenosis in the later stages of failing compensation; as, however, the different causes of pronounced difficulty in breathing are dealt with in the article upon DYSPNOEA (p. 246), the present article confines itself to minor degrees of the symptom, and particularly to the type of case in which the patient complains that he is comfortable when at rest but that he suffers from shortness of breath on exertion. The kinds of conditions under which this is the complaint may be summarized as follows:—

1. **Age:**—Extreme youth. Old age.

2. **Being out of Condition as the Result of:—**

Sedentary life
Over-eating—obesity
Over-indulgence in alcohol
Tobacco smoking
Under-feeding: poverty, indigestion, gastrectasis, gastric or duodenal ulcer
Having been ill—convalescence

Chronic toxæmia, from such things as: Dental sepsis, septic tonsils, intestinal toxæmia, coli bacilluria, cholecystitis, latent or chronic phthisis, trench fever, insidious infective endocarditis, plumbism

Sexual over-indulgence
The effects of gas fumes, petrol fumes, gases used in manufacturing process
Drug habits—morphia, cocaine, heroin, acetanilide, etc.

3. **Anæmic States of any Kind** (see ANÆMIA, p. 25).

4. **Polycythæmia** (p. 650).

5. **Altitude:**—

Living at heights
Descending to depths

Ascending to heights: Climbing; aeroplane work

Coming from depths to normal levels.

6. **Sulphæmoglobinæmia.**

7. **Methæmoglobinæmia.**

8. **Living in Vitiated Atmosphere.**

9. **Cardiac Conditions:**—

D.A.H. (disordered action of the heart, soldier's heart)
Valvular disease of the heart

Myocardial affections of the heart

Atheroma of the coronary arteries
Adherent pericardium.

10. Pulmonary Conditions :—

Emphysema
Bronchitis
Asthma

Phthisis
Latent pleural effusion
New growth of lung
New growth of bronchus

New growth of mediastinum
Aneurysm of the aorta affecting the lung.

11. After Injury to the Chest.**12. Deformity or Fixation of the Chest :—**

Rheumatoid arthritis
Lateral curvature of the spine

Former rickets
Spondylitis deformans.

13. Exophthalmic Goitre.**14. Functional Nervous Conditions.**

There is little need to discuss all the above in detail : the history, the state of the blood, the results of physical examination will lead to the correct diagnosis speedily in most cases. The chief difficulties arise when it becomes a question of deciding whether in a given case the cause is of minor or of major significance—simple obesity, for instance, or emphysema, or grave myocardial degeneration or coronary artery disease ; or again, over-indulgence in tobacco, or carcinoma of the lung ; and so on. One can only come to

a conclusion sometimes as the result of clinical intuition and experience, and even with these one is often wrong, serious trouble underlying some cases that at first seem trivial, and nothing material happening in others that for a time seem grave.

The difficulties are lessened if all methods of diagnosis are employed and nothing is left to chance ; physical examination of the heart and lungs is admirable up to a point, but negativity of abnormal physical signs does not signify normality of the intrathoracic organs, and it is important not to omit skiagraphic examination of the chest both anteroposteriorly and laterally in any case in which there is the slightest doubt : one may thereby detect sometimes latent phthisis, unsuspected aneurysm, or new growth ; *Fig. 105*, for example, is from a case of obscure ill health with shortness of breath on exertion in which there were practically no abnormal lung signs to suggest that there was so large a primary carcinoma of the lung ; the diagnosis, suggested by the skiagram, was confirmed by histological examination.

The greatest difficulties of all arise when it has become a question as to whether, when shortness of breath on exertion is complained of, the cause is

Fig. 105.—Skiagram of the thorax showing a large primary carcinoma of the left lung. The globular outline of the abnormal shadow to the left of the heart is characteristic, and so also is the clarity of the costophrenic angle below the growth. The patient was aged 52. The symptoms were vague, and the abnormal physical signs in the chest remarkably slight. The skiagram was taken in the course of a routine examination, and the discovery of the growth was unexpected. The chief complaint had been shortness of breath, which had been increasing. The diagnosis was verified histologically. (*By Dr. E. Talbot Nuttall.*)

the heart or something else. It is easy to comfort the patient by assuring him that his heart is all right and that his symptoms are due merely to indigestion or to wind round the heart, but the friends have fault to find when the patient falls dead in the street a few weeks later ; on the other hand, it is even worse to tell the patient that his heart is so affected that he must have a carrying chair to take him up to bed, when all that is wrong is over-smoking and lack of exercise, the patient living an invalid's life perhaps

for twenty years or more before he dies of something else with a perfectly normal heart. From the patient's point of view the latter type of error in diagnosis is the more to be deprecated, but it is no easy thing sometimes to be sure which view of the two to take—does the heart-state matter or does it not? Electrocardiographic records may be of assistance in deciding (see PULSE IRREGULAR, p. 663); so also may skiagrams, which serve to give the precise size of the heart far better than do any methods of palpation or percussion. Even so, however, all difficulty is not overcome, for a patient may have serious disease of the coronary arteries and yet yield normal electrocardiographic tracings and exhibit no skiagraphic evidence of abnormal size of heart. There is no easy way of being absolutely certain, but one would say in general that the older the patient and the more recent the symptoms the greater should be the respect, from a cardiac point of view, that one pays to the significance of the symptom of shortness of breath on physical exertion; whilst, conversely, the younger the patient, and the longer-standing the symptom, the less serious need be the view that one takes. Disordered action of the heart (D.A.H. or soldier's heart) was very common in the army; it is really almost as common in civil life, but it is brought out less markedly when there is not the stress of war to reveal it; it may result from intrinsic nervousness, or from minor causes of upset of the sympathetic nervous system such as worry, fear, toxic states, recent illness such as influenza or trench fever; but it does not kill, does not need cardiopathic treatment, and does not indicate heart disease or call for its restrictions. It is often associated with precordial pain, a pulse-rate that is above the normal and easily accelerated; but electrocardiograms are normal, skiagraphy indicates a heart of normal size, and any bruit that may be present is of a dubious type and not forthwith indicative of organic valvular disease. Experience helps much in relegating cases of shortness of breath on exertion due to this type of condition to the proper category, but there is grave danger of giving the patient the impression that the heart is 'weak', 'flabby', 'dilated', or otherwise really wrong when it is not.

On the other hand, in patients who approach the age of sixty whose health has hitherto been perfect, the fact that there is beginning to be trouble when a walk is taken up an incline, though walking on the flat is still easy enough, merits great respect; for it may be the earliest indication that there is grave myocardial change—fibroid or fatty—recognizable perhaps by electrocardiography or skiagraphy; or of coronary artery disease, which is more difficult to exclude. Such cases leave one with a sense of anxiety even when one can find absolutely nothing wrong, and it is from this group that so many instances of sudden death, or of death in sleep, are derived. One is bound to treat with respect each case in which, in advancing age, shortness of breath on going up an incline begins to be more and more a trouble to the patient; whilst on the other hand in young persons complaining of the same symptom one may safely tend to regard the condition as due to neurocardial rather than to valvular or myocardial changes unless there is some potent sign or clinical evidence to the contrary.

Testing the effort syndrome is often helpful; broadly speaking there is an average difference of about five beats per minute between sitting and standing; the effort of walking briskly up a flight of stairs and down again may increase this difference to somewhere about fifteen or twenty beats a minute, though in D.A.H. cases and in tobacco smokers the increase may be more; whilst the patient sits still in a chair after the exertion a reasonably healthy heart should resume its resting frequency in about three minutes. Nervousness, however, may influence some cases so much that even the effort-syndrome test is not easy of interpretation; during life insurance examination, for example, the proposer may be short of breath from coming up the stairs, and may have a pulse-rate over 100 per minute throughout the examination without there being anything wrong with the heart at all. There is no fixed rule that applies to all cases.

If exertion removes an irregularity of rhythm observed during resting, it is generally safe to assume that the heart is muscularly in a reasonably good state of health.

Short of actual failure of compensation, indicated by other features of the case, patients suffering from organic valvular heart disease exhibit shortness of breath on exertion to a much less degree than might be expected; often not at all, and almost invariably to a less degree than do patients with D.A.H.

Herbert French.

BREATHING, CHEYNE-STOKES.—(See CHEYNE-STOKES RESPIRATION, p. 138.)

BREATHING, SLOW.—(See BRADYPNEA, p. 110.)

BRITTLE BONES.—(See FRACTURE, SPONTANEOUS, p. 304.)

BROMIDROSIS.—(See SWEATING, ABNORMALITIES OF, p. 803.)

BRUITS, CARDIAC.—When a murmur is heard to accompany or follow one or other of the cardiac sounds, its significance can only be determined by noting the place and time at which it occurs, and the other evidences of disease that accompany it. Murmurs heard in the neighbourhood of the heart may be: (I) *Exocardiac*; (II) *Cardiac*.

I. EXOCARDIAC BRUITS.

Apart from the sounds of pericardial friction, seldom described under the title of murmurs, the chief clinical importance of these exocardiac sounds rests in their liability to be mistaken for signs of cardiac disease. Their actual origin is uncertain. There is some reason to think that the cardio-respiratory murmur, perhaps the commonest type of exocardiac bruit, is a sign of pleurisy, being in fact a kind of pleuro-pericardial friction. The loud 'slate-pencil' squeaks sometimes heard over the lower precordium are almost certainly set up by roughenings of the endothelial surface of the pericardial sac. The sharp clicks heard over the various parts of the heart originate, perhaps, in the alveoli of flattened and collapsed lung-edges bordering on the precordium; and some of the exocardiac bruits heard at the base of the heart in children also appear to be due in some way to pulmonary collapse. But it is very seldom indeed that the discovery of an exocardiac bruit contributes materially to the diagnosis of any of these lesions. Nevertheless, a recognition of their origin in such lesions is of real help in distinguishing between exocardiac and true cardiac bruits.

Generally, however, it is by observation of its inherent characteristics that we discover the exocardiac origin of a murmur: (1) They vary notably with respiration. If a murmur is heard clearly in inspiration and not at all in expiration, its exocardiac origin is certain. (2) They vary also with the posture of the patient. True mitral murmurs are almost always louder when the patient is lying down than when he is standing up, but the reverse is usually true of exocardiac murmurs. (3) Exocardiac murmurs often arise at an anomalous point in the cardiac cycle. This is especially so in those that arise during systole: they are apt to begin quite late in the systole, just before the second sound, in fact. (4) They are sometimes heard very clearly over a limited area, yet not at all in the neighbourhood of that area. This sharp transition from clear audibility to silence should arouse suspicion as to the exocardiac nature of a murmur. (5) There is often a superficial quality about such murmurs that almost defies analysis, but may perhaps be expressed by saying that they sound nearer to the observer's ear than the heart-sounds.

Among the whole group of murmurs that conform to these generalities, certain particular types can be more or less clearly distinguished. The commonest of these is the cardio-respiratory murmur, so often heard over a heart that is beating quickly. It is always systolic in time, and loudest during inspiration. In its most typical form it occurs two or three times to each inspiration and sounds like a series of jets or puffs synchronizing with the heart's beat. Usually it is louder when the patient stands up than it is when he lies down. It is heard best at the apex of the heart, also over the edges of the precordium, and below the inferior angle of the left scapula. More often, perhaps, than any other kind of exocardiac murmur, it is mistaken for a sign of organic disease, since it simulates the apical systolic murmur of mitral incompetence. During the war this mistake must have deprived the British Army of battalions of able-bodied men.

The other kinds of exocardiac bruits are less likely to be mistaken for signs of organic disease, except for the systolic murmurs sometimes heard over the pulmonic area in children with a collapsed and partially retracted left lung. These may be wrongly interpreted as evidences of a congenital hypoplasia of the pulmonary artery; but they are heard only over a limited area, and vary much with posture and respiration.

PERICARDIAL FRICTION.

This kind of 'bruit' is in a category of its own. It arises neither in the heart itself nor in structures separate from the heart; its particular qualities are different from those of the generality of exocardiac sounds on the one hand and of endocardiac murmurs on the other; and its recognition has a positive as well as a negative clinical value. Briefly, its chief features are its obviously superficial 'near-to-ear' origin; its brushing, rubbing, or creaking quality; its distribution, over an area that never exceeds that of the precordium, and may be limited to small parts of it, particularly over the aortic and pulmonic areas; and its time-relations. Characteristically it is a 'to-and-fro' sound, heard in both systole and diastole, so that it may occasionally simulate the bellows murmur of aortic disease. Sometimes it is heard only in systole, seldom in diastole only. Its most constant time characteristic is that it is separated from the true sounds of the heart, first and second sound alike, by a little interval; as if it were trying hard to keep step with the cardiac sounds, but always just failing. Often pericardial friction may be intensified by pressing the chest-piece of the stethoscope firmly down on the thoracic wall.

II. TRUE CARDIAC BRUITS.

These may be general or local, i.e., their origin may lie in some general cause operating on the heart as a whole, or in some lesion or malformation of the heart.

General Cardiac Murmurs. The two principal causes are anemia and toxæmia: for example, pernicious anemia and enteric fever. Such murmurs as these, like their causes, are general; that is to say, they are heard all over the heart. Observation of this fact alone should arouse suspicion as to their nature. Other points of value in diagnosis are their soft and blowing character, and the fact that they are as a rule louder at the base than at the apex of the heart. Often, also, similar bruits are to be heard over the great vessels of the neck. The diagnosis is clinched by observation of other symptoms of the causal disease, and by failure to discover other evidences of structural disease of the heart.

Local Cardiac Murmurs are very valuable signs of organic disease of the heart; and it is because they are thus valuable, and because a diagnosis of cardiac disease is so ominous, that it behoves us not to accept it until the alternative possibilities discussed above have been adequately weighed. But if this has been conscientiously done, and the bruit cannot be dismissed as exocardiac or general, the next step is to discover in what part of the heart's channel the vibrations, heard as a bruit, are formed. Acquired disease of the left heart is responsible for a vast majority of true endocardiac bruits, and we may therefore consider these first.

Mitral Murmurs may be systolic or diastolic or both. The *mitral systolic* is the commonest of all cardiac murmurs, even after we have excluded the exocardiac murmurs that imitate it and the general cardiac murmurs of which it is but a part. It is caused by incompetence of the mitral valve, which fails to prevent reflux from the left ventricle into the left auricle during ventricular systole. This incompetence lies in the failure of the valve curtains to come together during ventricular systole; either because the curtains themselves are deformed and shortened by disease, or because the left auriculo-ventricular ring is stretched so wide that they can no longer guard the whole of it. Whichever the cause, the intrinsic characteristics of the murmur are that it is heard with maximum intensity at or close to the point of maximum impulse, diffusing thence to the left rather than to the right; and that it is truly systolic, following close after the first sound, which it may indeed largely replace. Instinctively, also, we recognize that the murmur arises at the same depth below the chest wall as the cardiac sounds themselves. In pitch and intensity it may vary widely, from a scarcely audible whisper to a loud hiss or buzz; and in duration, from a mere softening of the end of the first sound to a series of vibrations which only die down just before the second sound is heard. Neither loudness nor duration is proportional to the severity of the disease. Disappearance of a mitral systolic murmur is sometimes due to enfeeblement of the ventricular muscle lessening the force of the regurgitant flow. Mitral systolic bruits are usually louder during expiration than inspiration, presumably because inspiration, expanding the lung, brings it forward between the heart and the chest-piece of the stethoscope. Possibly for a similar reason, the mitral

systolic bruit is louder when the patient lies down than when he stands up; and it is louder when he lies on his left side than when he lies flat on his back.

There is no feature of the murmur itself by which we can determine whether the incompetence is muscular or valvular, except that it is probably the latter if it is very harsh. The diagnosis between the two conditions can only be made by diagnosis of the general state of the heart. Indeed, the truth is that a diagnosis of 'mitral incompetence' is no more satisfactory than a diagnosis of 'glycosuria'. Each is often the leading feature of a case; but the true diagnosis takes account of causes rather than symptoms. Mitral incompetence may be a feature of cardiac rheumatism, cardiosclerosis of senile or hypertietic type, endocardial ulceration, and so forth; and the establishment of its existence is but a step to the diagnosis of the lesion that has caused it.

It is simulated by:—

1. Exocardial bruits, especially of the cardio-respiratory type. This mistake is often made, and to realize this is to avoid it, for it will lead to examination of the patient lying down as well as standing, and to observation of the effects of respiration on the bruit. It must also be realized that the cardio-respiratory murmur is often audible below the angle of the left scapula, so that it is a fallacy to regard 'transmission' of an apical systolic murmur to the back as a proof of its organic origin. A diagnosis of mitral disease should never be made on the basis of an apical systolic murmur alone; there must be other evidences of change in the structure of the heart.

2. General or 'hæmic' bruits; but these are so often louder at the base than at the apex than it is not an easy mistake to make.

3. The murmur of patent interventricular septum. This, however, is heard with maximum intensity well to the right of the point of maximum impulse, and nearer to the left border of the sternum than to the left mammary line.

4. The tricuspid systolic murmur, which also is more centrally placed than mitral murmurs generally are.

Mitral diastolic murmurs are, speaking in general terms, due to obstruction of the stream flowing through the left auriculo-ventricular channel, by fibrous changes in the mitral curtains drawing them closely and inseparably together. They are heard best at or immediately internal to the point of maximum impulse, and usually over a narrowly restricted area. The murmur may be mid-diastolic only; or it may be heard only immediately before the next following first sound, or it may run right through from the mid-diastolic point to the end of diastole. A diagram (*Fig. 106*) will serve to make this variation clear. This shows that the different types of mitral diastolic murmur arise from different phases of that mitral fibrosis which is so constant and dominating a feature of cardiac rheumatism. The most characteristic phase of that process is 'mitral stenosis' in which the auriculo-ventricular channel is reduced to a narrow chink; and the most characteristic sign of that phase is the mitral presystolic murmur. This consists of a series of loud, coarse vibrations leading up to and ending in a loud sharp first sound, their intensity appearing to increase progressively to a climax, reached as they disappear into the first sound. This murmur is so striking a sign of disease that its recognition is a matter of the first importance. It may therefore be well to give a little attention to the mistakes commonly made in its detection.

- a. It is not looked for in the right place. If the apex beat is carried out to the axilla by morbid enlargement of the heart, the presystolic murmur will go with it; and it is useless to search for it in such a case in the neighbourhood of the nipple, particularly as it is as a rule audible over a limited area only.

- b. The patient is examined standing up only. Often a presystolic murmur, not heard under these conditions, becomes distinctly audible when the patient lies down. Sometimes it is only found when the patient lies down on his left side, while in others a short spell of exercise will render audible a murmur about which there had previously been a legitimate doubt.

- c. Often a presystolic murmur is wrongly thought to be present, when there is in fact no more than a blurring of the first sound accompanying rapid action of the heart. This is a very serious mistake, and one which should never be made. The only way to avoid it is to examine the patient carefully in all positions, and in particular to search for other signs of mitral stenosis. If there is neither accentuation of the first sound at

the apex nor of the second sound at the base, a diagnosis of mitral stenosis ought not to be made.

d. A good many mistakes arise from an imperfect realization of the fact that the presystolic murmur is, though undoubtedly the most characteristic, yet by no means the only kind of diastolic murmur arising at the mitral orifice. This is already displayed in *Fig. 106*, and one need only repeat that bruits at the mitral area may be continuous from diastole into presystole, or may not begin till presystole; that in either of these varieties the characteristic crescendo form is present; but that in other cases the bruit may end before presystole is reached, remaining limited to mid-diastole. On the other hand, this mid-diastolic bruit may represent a phase of mitral disease earlier than that in which the characteristic presystolic murmur is heard. Such murmurs are commonly associated with reduplication of the second sound at the apex. Often they are quite short in duration and limited in area, and therefore are difficult to catch. As the valvular fibrosis progresses the murmur lengthens, though in many instances it never reaches into the presystolic phase why, it is not clear. On the other hand, presence of a mitral diastolic with absence of a presystolic murmur may represent an advanced phase of disease; when associated with total arrhythmia, it always means that auricular systole has failed, and with it the vibrations that it is apt to cause at a constricted mitral opening.

e. There remain those difficult and controversial questions that have arisen over the co-existence of a presystolic apical murmur with aortic regurgitation. Firstly, an aortic diastolic murmur may be heard low down at the mitral area, so late in the cardiac cycle as to imitate the mitral presystolic murmur. Secondly, in cardiac rheumatism aortic incompetence often co-exists with mitral stenosis. Thirdly, in a few instances a true presystolic murmur has been heard in the presence of aortic incompetence where no mitral stenosis existed; this is the Austin Flint mur-

mur, but it is very rare, and nearly all the so-called Flint murmurs belong to one of the other two classes. The broad rule to follow is to recognize every murmur that is really presystolic as evidence of mitral stenosis, except when the nature of the disease makes it unlikely that the mitral valve is fibrosed; for instance, in cardiac syphilis. The more nearly the murmur approaches to that heard in Phases III and IIIa of *Fig. 106*, the more likely it is to be due to true mitral stenosis. Murmurs such as those depicted in Phases II and IIa may be heard at the apex in connection with aortic reflux.

Aortic Murmurs may also be systolic or diastolic, or both.

Systolic murmurs heard at the aortic area may signify: (1) Nothing definite; (2) Aortic atheroma with roughening of the cusps; (3) Aortic stenosis; and (4) Aortic aneurysm.

Neither (3) nor (4) should ever be diagnosed on the strength of an aortic systolic murmur alone, no matter how loud it is. Other signs of the lesions concerned must be found in order to justify such a diagnosis. But when it comes to nice distinctions between (1) and (2) or between (2) and (3), the louder the bruit, the further it carries into the

Fig. 106.—MITRAL FIBROSIS.

carotids and subclavians, and the more clearly it is heard in the interseapular region, the greater the possibility that it arises from gross disease of the aortic cusps.

If there is a diastolic as well as a systolic bruit at the aortic area, it affords very strong evidence of the origin of the latter in disease of the aortic valves. The ultimate diagnosis, however, is not anatomical only but also etiological. If a murmur is heard at the aortic area, are there any other signs of cardiac disease? If not, the murmur may be disregarded, unless it is very loud and gross, when other signs of disease should be watched for carefully. If there are other signs, do they point to a diagnosis of cardiac rheumatism, cardiac syphilis, or cardiosclerosis? It is impossible to discriminate between these possibilities by reference to the characters of the bruit alone.

These generalizations are true also of *aortic diastolic murmurs*: with this difference, that the presence of an aortic diastolic murmur is sure evidence of organic disease of the aorta, of its demilunes, or of both. Because it is so it is well to take a good deal of trouble before making up one's mind as to the presence or absence of an aortic diastolic murmur. The patient should be examined in all positions. Sometimes an aortic diastolic bruit can only be heard when the patient stands: occasionally it becomes audible only when he leans forward: and it may even be necessary to put him in a knee-elbow position to render his aortic diastolic bruit audible.

It is often heard, not at the aortic area itself, but down the left sternal margin. Indeed, the aortic diastolic bruits of rheumatic heart disease are more often heard here than at the second right interspace. The reverse is true of cardiac syphilis: in this disease aortic diastolic bruits are usually heard loudest at the aortic area itself.

As a rule the true aortic diastolic murmur has a curious distant quality, and it is this softness that sometimes makes it difficult to hear. It may follow or replace the second sound at the base. The further down it is followed towards the cardiac apex, the later in the diastolic phase is it heard. Rarely, it is heard at the cardiac apex only: its aortic origin can then be determined only from the presence of other signs of aortic disease.

Aortic diastolic murmurs are simulated by (*a*) pericardial friction, (*b*) the diastolic murmur of pulmonary regurgitation.

Neither of these errors is very likely to be made, and a discussion of means of avoiding them is academic rather than practical. What is of more importance is to insist on the need for searching carefully for the cause of any aortic diastolic murmur that may be heard. Is it due to cardiac rheumatism, to endocardial ulceration, to cardiac syphilis, or to aortic atheroma? The first two lesions only cause incompetence by a direct action on the aortic cusps: the other two may render the valve incompetent, either by a similar direct action on the cusps or by injury to the aortic wall and stretching of the aortic ring, or both. Yet it is not safe to rely on this generalization to distinguish between the one and the other kind of lesion: for in cardiac rheumatism leakage through the aortic valve may establish a dynamic dilatation of the aorta, so that the co-existence of aortic dilatation

with aortic leakage may appear here as in aortic syphilis and atheroma. It is by remembering that we have no right to rest content with a diagnosis of 'aortic incompetence' merely, and forcing ourselves to search into every feature of the case, that we shall secure an etiological diagnosis on which to base prognosis and treatment.

Tricuspid Murmurs. Bruits arising at the valvular orifice of the right side of the heart are far less often encountered. Neither systolic nor presystolic bruit should be ascribed to disease or disorder of the tricuspid valve unless it centres very definitely on the tricuspid area and away from the mitral area. So often bruits that arise at the mitral area are audible as far as and even beyond the tricuspid area, but in these the maximum intensity of the vibrations is discovered to lie at or near the mitral area. If, however, it should be found to lie very definitely at the tricuspid area, i.e., immediately to the left of the base of the ensiform cartilage, a suspicion of its tricuspid origin may reasonably be entertained. Loud bruits of tricuspid origin, whether systolic or presystolic, are sometimes due to actual tricuspid fibrosis, not so often as one might expect to stretching of the valve. This latter, though often found post mortem, rarely produces vibrations that can be distinguished clinically.

Pulmonary Murmurs. *Systolic bruits* are often audible at the pulmonic cartilage. Most of them are hæmic; some are exocardiac; a few are due to congenital hypoplasia

of the pulmonary artery. These last are to be separated from the others by the rules already laid down for the discovery of hemic and exocardiac murmurs: that is to say, unless there is the most obvious evidence of congenital malformation of the heart, no pulmonary systolic bruit should be accepted as evidence of disease until these alternative explanations have been adequately considered. The louder the bruit, the further it penetrates to the left clavicular, supraclavicular, and suprascapular regions, and the more obvious the thrill that accompanies it, the more likely it is to owe its origin to a malformation of the pulmonary artery; but it is seldom safe to make a diagnosis of malformation unless, in addition to the murmur, one can discover evidence of imperfect aeration of the blood, or of enlargement of the right ventricle (*Figs. 107, 108, 109*), or of the presence of some other congenital malformation of the heart.

Pulmonary diastolic murmurs are exceedingly rare: as a result of disease of the pulmonic semilunar valves they are so rare that it would scarcely ever be justifiable to ascribe a murmur to this cause. More often they arise as a result of mitral obstruction forcing up the pressure in the pulmonary artery to a point at which its valves are compelled to leak. But it is a great mistake to suppose that every basic diastolic bruit heard in a patient with mitral stenosis arises in this way. A majority of such bruits owe their existence to the fact that the same rheumatic process that is responsible for causing mitral obstruction also sets up cicatricial changes in the aortic valves. The amount of

Figs. 107, 108. Skelagrams illustrating (A) right and (B) left ventricular hypertrophy. By skelagramy it is possible to detect right ventricular hypertrophy that might otherwise escape notice, and thus secure information of value in the diagnosis of congenital cardiac malformation.

aortic leakage thus induced may be only just enough to cause a faint aortic diastolic bruit, heard as is the rule in cardiac rheumatism down the left sternal border, and not enough to alter the form of the pulse wave: and this bruit is often misinterpreted as evidence of pulmonary leakage. It is doubtful whether a diagnosis of secondary pulmonary regurgitation is ever justified except where there are obvious signs of extreme overloading of the lesser circulation as a result of mitral obstruction.

Murmurs at Abnormal Intracardiac Orifices. The chief of these murmurs result from *patency of the interventricular septum* at the pars membranacea, which may occur alone or in connection with imperfect development of the pulmonary artery. The murmur characteristic of this anomaly is heard over the middle of the precordium, the centre of its area of propagation lying near to the inner end of the fourth left interspace. It is usually systolic, but may run on into the second sound. Often it is accompanied by a thrill. Though loud at its point of maximum intensity, this loudness decreases rapidly as one passes away from that maximum point towards the edge of the precordium, so that the murmur may be quite inaudible outside a circle of two inches' radius from its maximum point. It alters little with changes in the patient's posture.

Interauricular foramina are the commonest of all cardiac malformations, but they do not cause murmurs. That much less common anomaly, *patency of the ductus arteriosus*, is the source of a highly characteristic bruit. This is heard below the left clavicle and internal to the left scapula. It is a long-drawn rumble persisting throughout systole and diastole, rising to two maxima of intensity with each of the cardiac sounds. Though difficult to describe, it is easy to recognize and reliable as a basis of diagnosis.

Certain Vascular Bruits may also be mentioned. Over an *aortic aneurysm* a systolic bruit may be heard. If it stretches open the aortic ring, a diastolic bruit is also added. If the sac opens into the superior vena cava, the loud humming of an arteriovenous aneurysm is produced. If it opens into the pulmonary artery, a harsh bruit continuous through systole and diastole may result.

Fig. 108.—To illustrate 'right ventricular preponderance' in the electrocardiogram. This 'right preponderance' may be of service in the diagnosis of right ventricular hypertrophy and therefore of congenital malformation of the heart.

Fig. 109.—Electrocardiogram illustrating 'left ventricular preponderance', for comparison with *Fig. 108*. Note the downward R in *Lead 1* of *Fig. 108*, and in *Lead 3* of this figure.

In children, healthy and otherwise, up to the age of ten, a venous hum is often audible just below the sternoclavicular joints. It is loudest in systole, but runs on into diastole; it is increased by inspiration and also by retraction of the head. It has no clinical significance; neither has the blowing jet-like systolic murmur heard below the clavicles, the left more often than the right, in many adults. It is increased by inspiration, also by lifting the arm to a right angle with the long axis of the trunk. Probably it is caused by compression of the subclavian artery between the first rib and the clavicle.

The Course and Development of Cardiac Murmurs must be noted. As a rule there is no great change in organic murmurs even when they are watched for a considerable time, and marked alterations should prompt a suspicion as to the organic basis of a murmur. In fact, organic murmurs only undergo abrupt change when the lesions that cause them change abruptly, as, for example, when a diseased aortic valve that has hitherto caused little or no abnormal vibration bursts under some sudden stress and a loud systolic or diastolic murmur is immediately noticed. In the writer's experience, the tendency to change that is said to characterize the murmurs of ulcerative endocarditis is seldom of actual diagnostic value; the only exception being the addition of an aortic diastolic murmur to already existing signs of mitral disease. This, if accompanied by the toxic and embolic symptoms of endocardial ulceration, may be of value in diagnosis.

In conclusion, one or two aphorisms as to the general place of bruits in the diagnosis of cardiac disease may be added :

1. The patient should always be examined lying down as well as standing up; usually, also, in the left lateral as well as in the supine position.

2. All the other physical signs and symptoms must receive due consideration. It is a wholesome exercise to attempt diagnosis of cardiac lesions without using the stethoscope at all.

3. If there is any doubt as to the meaning of a murmur, more than one examination should be made before the patient is told that he has cardiac disease. *Carey Coombs.*

BULLÆ. A bulla is literally a water-bubble : it is synonymous with bleb or blister ; it differs from a vesicle only in its size, which may be from half an inch in diameter to that of a tangerine orange or more. Almost any vesicular skin disease may be of bullous degree occasionally ; there are certain diseases in which bullæ are characteristic ; and there are yet other affections in which, although bullæ are not always present, they may occur sometimes in a marked degree. The following are the chief conditions under which bullæ are, or may be, a prominent feature of the case :—

1. Conditions in which Bullæ are usual :—

Pemphigus	Herpes gestationis	Pemphigus neonatorum
Erythema bullosum	Erythema iris	Cheirpompholyx
Dermatitis herpetiformis	Epidermolysis bullosa	Hydroa æstivale.

Local application of vesicants, such as cantharides, arnica, rhus toxicodendron, croton oil, nitric acid, scalding water, hot solids ; or from exposure to extreme cold, as in frostbite or after freezing with carbon-dioxide snow.

Local friction by splints after fractures ; or by boots, oars, tools, etc.

2. Conditions in which Typical Bullæ may occur, though they are not usual :—

Erysipelas	Syphilis	Infants with maladies which
Impetigo contagiosa	Syngomyelia	in adults would be vesicular ; e.g., Herpes zoster
Iodism	Gangrene	(Fig. 110).
Bromism	Raynaud's disease	
Glanders	Scurvy	

Extreme œdema from Bright's disease or heart failure.

Workers amongst turpentine, chrysarobin, varnish, aniline dyes, and other chemicals ; tar products, resin, volatile oils ; satin-wood, primula obconica, and some other plant products.

Poisoning by large doses of certain hypnotic drugs, notably veronal, antipyrin, acetanilide, especially towards the end of a fatal case.

The diagnosis is sometimes obvious : for instance, *herpes gestationis*—also known as hydroa gestationis, erythema gestationis, and dermatitis pruriginosa polymorpha recurrens graviditatis—is probable when a bullous eruption develops in a pregnant woman ; and the diagnosis is certain if there is a history of former pregnancies associated with a similar eruption, with complete freedom from the complaint between the pregnancies. The eruption itself is precisely similar to that of dermatitis herpetiformis, described below, and there is generally eosinophilia (p. 127). In most cases the trouble begins in the later months of pregnancy, but tends to develop earlier in each successive pregnancy ; and whereas in most cases it subsides rapidly when the child is born, in a few instances it may last into the puerperium, or even develop only during that period. The most troublesome part

of the complaint is the itching and irritation, which often amount to actual pain. A person subject to pemphigus or erythema bullosum might develop an attack during pregnancy; but herpes gestationis is excluded if recurrence takes place apart from pregnancy, whilst the occurrence of the bullous eruption solely in association with pregnancy makes the diagnosis obvious.

Bullæ in an infant generally receive the term *pemphigus neonatorum*, but the eruption is not related to ordinary pemphigus, so it is a pity the word pemphigus is employed at all. There are two distinct varieties, namely: (1) That in which the bullæ are chiefly on the hands and feet, one of the manifestations of a severe and generally fatal type of congenital syphilis, in which the eruption appears almost immediately after birth instead of after an interval of days or weeks, as in other cases; and (2) That in which there is an infection of the skin of the nature of impetigo—generally staphylococcal, but in some cases due to less usual organisms such as the *Bacillus pyocyaneus*—producing bullæ instead of the more common pustules; the latter is an affection of poverty-stricken districts, occurring in more or less epidemic form, sometimes closely related to the practice of a particular midwife, and fortunately rare nowadays.

FIG. 119. Two views of the left arm of a child, age 2½, affected severely by herpes zoster, showing that eruptions which in older subjects are generally vesicular in nature at a tender age take the form of blisters.

Cheropompholyx may generally be recognized at once. It is a dysidrosis, and the sweat-glands of the palms and soles are most affected, though those of the forehead, chest, and back may sometimes be affected too. As a rule the sweat retained in the glands produces subcutaneous vesicles that are barely larger than sago grains: as the superficial epidermis wears off the little sweat-cysts reach the surface, a process assisted by the scratching that usually results from the accompanying irritation. After each cyst bursts there is desquamation which may simulate that of scarlatina. The malady occurs in summer weather, or in tropical climates, especially in those who perspire freely.

Blisters produced by vesicants are diagnosed readily when it is known that any application is being used. Difficulty arises mainly in two classes of persons, namely: (1) In those who live in houses upon which the *Rhus toxicodendron* is grown as a virginia creeper, the nature of the case being discovered usually from the fact that the patient is always affected when at home, and never when away; and (2) In hysterical patients, or in malingerers, who produce the skin eruption surreptitiously. If the latter is suspected it is generally possible to place the patient under conditions which preclude self-application, when the disappearance of lesions confirms the diagnosis; or the actual vesicant employed may be discovered, liquor epispasticus for instance, or some other preparation of cantharides; croton oil; capsicum; carbolic acid; mylabris; iodine; or one of the strong mineral acids, especially nitric acid.

The relationship of occupation to a bullous dermatosis may become obvious from the way the skin trouble recurs whenever any particular work is resumed: the list above indicates the kind of occupations that are liable to produce it; nearly all these produce bullæ far less often than they do a vesicular dermatitis.

Extremely œdematous tissues are easily blistered, and on this account one must be

chary of diagnosing anything but simple blisters when bullæ develop upon or dermatous legs or other parts in association, for instance, with *Bright's disease*, or in *chronic heart cases* with failing compensation. The same applies to the blebs arising on the skin of *fractured limbs*, and also in the region of a local *gangrene*; or necrosis of the soft parts due to such causes as *frostbite*, *Raynaud's disease*, or *scurvy*. The diagnosis in these cases will nearly always be clear enough, and so will it be in cases of simple blisters due to friction.

Having thus excluded the more obvious cases, there remain: pemphigus, erythema bullosum, dermatitis herpetiformis, erythema iris, epidermolysis bullosa, erysipelas, impetigo contagiosa, iodism, bromism, glanders, syphilis, and syringomyelia. Of these, acquired *syphilis* is so seldom bullous that it would not be diagnosed unless there was strong collateral evidence of the nature of the complaint. *Syringomyelia* is rare also, and bullæ occur in but a small proportion of the cases; should they do so they will attract attention from being confined to a local area, the fingers and hands for instance, leaving the rest of the person free. The diagnosis is confirmed by finding cutaneous sensibility natural, though the patient cannot distinguish pain from touch, or heat from cold, in the affected parts. The cutaneous affections of syringomyelia are known as Morvan's disease. The lesions arise because the skin is insensitive to things that are painful or hot enough to produce sores and blisters.

The patient's occupation may suggest the malady in a case of bullous *glanders*: a horse with which the patient had to do might be known to be affected with the complaint. The skin eruption is sometimes quite a late manifestation of a prolonged and obscure febrile illness when the glanders infection has started internally, for instance in the lungs. The *Bacillus mallei* may be found in direct smears from the contents of the bullæ, or in cultures from them. Bacteriological methods afford the final criterion of glanders.

Both *bromides* and *iodides* may produce various types of skin eruptions. The commonest is simple acne-like pustules without the blackheads of ordinary acne vulgaris; but there may be a patchy erythema with cutaneous infiltration or nodular swelling studded with yellow points from which thick puriform fluid can be expressed; or a confluent furuncular lesion; or a true bullous eruption or hydroa. The latter is decidedly rare, but its occurrence should be borne in mind, and inquiry made as to any drugs that the patient may be taking. In the case of iodides the urine gives a bluish-green colour with the guaiacum test, though no blood is present, and if there is still doubt a quantity of urine may be evaporated down, and either bromine or iodine detected by ordinary chemical tests. Bromide and iodide eruptions have been recorded in infants at the breast when the mother has been taking the drug without presenting any cutaneous symptoms herself.

Bullous *impetigo contagiosa* is a variety of impetigo. Fluid accumulates in the infected spots so quickly that at first it does not appear to be purulent, but rather to take the form of big vesicles or bullæ. These often become pustular, and as they dry up the crusts over them have a characteristic yellow honey-like appearance. The condition can be diagnosed, as a rule, from the fact that other parts of the body present the typical lesions of ordinary impetigo; there may be other patients affected in the same house or school, and the condition is as readily curable by antiseptic measures as is impetigo. There is a very rare and extremely grave disease described as *impetigo herpetiformis* in pregnant women; but this seems to be an aggravated form of dermatitis herpetiformis or herpes gestationis that has become purulent and contagious. It is found in Austria, but not, apparently, in England.

Erysipelas is a familiar cause of bullæ, and when blebs are present upon the typical tender, slightly raised, and well demarcated red skin at the height of the affection, in association with the constitutional symptoms and pyrexia, there can seldom be difficulty in the diagnosis. It is when the erysipelas is subsiding or has subsided, whilst the bullæ, or the remains of them, are still obvious, that difficulty might arise. Streptococci may be detected bacteriologically.

If all the above conditions can be excluded, and the patient is suffering from a disease of which bullæ with more or less erythema are the chief manifestation, then the diagnosis has been narrowed down to one or other of the following: pemphigus, erythema bullosum, dermatitis herpetiformis, erythema iris, and epidermolysis bullosa; there is evidence to show that these are closely related in some respects, the different names applying to affections that differ more in type than kind. If the patient develops bullæ on various parts of

the trunk and limbs without any erythema, or at any rate without any erythema until the bullæ have been present a longer or shorter time, the condition is described as *pemphigus*. If the bullæ develop, not on normal-looking skin, but upon places where there has already been erythema, associated with more or less itching, or even pain, before the bullæ develop, and if the whole eruption consists of this combined condition of erythema and large bullæ, the name used to designate it is *erythema bullosum*. If the bullæ tend to dry up at their central parts and then to be followed by a secondary ring of vesicles or blebs around the original one, these secondary vesicles being followed in turn by others upon a yet larger

ring outside them, the condition is referred to as *herpes iris* or as *erythema iris*, according as there is little or much erythema before the first vesicles or bullæ appear. When the bullæ are apt to develop on any part of the body from a degree of rubbing or scratching which in the ordinary individual would be quite unlikely to produce blisters, this undue tendency to blister formation from what ought to be inadequate causes is spoken of as *epidermolysis bullosa*, a condition which may persist throughout life without necessarily leading to any other untoward symptoms; it is probably related to factitious urticaria. *Dermatitis herpetiformis* is a polymorphous eruption, of which bullæ form but a part; the trouble begins with itching of the skin, and more or less general disturbance, part of which arises from the loss of sleep entailed by the irritation. In various parts of the body or limbs erythematous and urticarial patches supervene, some of which subside without further development, whilst upon others clusters of vesicles quickly appear. Many of the clusters contain twenty or thirty vesicles upon a single inflamed

Fig. 111. Hydroa festiva, showing the defective brown teeth associated with this condition.
(By kind permission of the 'Quarterly Journal of Medicine'.)

base; some, fewer vesicles of larger size; others develop into typical blebs varying in area from that of a sixpence to that of a half-crown. No region of the body is exempt. The characters of the lesion are precisely similar to those found in pregnant women suffering from herpes gestationis, but there must be a difference in causation, for the latter, though it occurs with every successive pregnancy in the same woman, remains in complete abeyance between the pregnancies, whilst dermatitis herpetiformis—Dühring's disease or hydroa—may occur in either sex and at almost any age, though it is less common in children than in adults. It is probably due to the action of some poison circulating in the blood, derived perhaps from the food in some cases; it is possible for two persons to be taken ill after partaking of the same food, one with acute gastro-intestinal

symptoms, such as diarrhoea and vomiting, the other with acute pemphigus; it looks, therefore, as if pemphigus and its allies may be related to the acute urticaria that is so familiar in certain cases of shell-fish poisoning.

Hydroa aestivale is a peculiar and rare congenital condition in which the patient's skin develops bullæ like those of pemphigus, but only during the summer months, the eruption being on the exposed parts; purpuric spots often appear between the bullæ. The hydroa may be the only evidence of idiosyncrasy, but sometimes the same individual exhibits porphyrinuria, with a tendency to brown pigmentation of the bones and teeth (*Fig. 111*).

Any one of the bullous dermatoses may be either acute, subacute, or chronic; in any of these degrees there may be practically no constitutional disturbance on the one hand, or the patient may be so ill with pyrexia (*Fig. 112*) and anorexia as to require to stay in bed; not a few such cases prove fatal. In all the bullous dermatoses the eruption may be restricted to the cutaneous surface; but the bullæ may also occur upon mucous membranes, especially of the mouth, palate, œsophagus, nose, colon, rectum, and vagina. Even when

Fig. 112. Temperature chart in a case of chronic pemphigus. The woman had had the bullous eruption on and off for a year, with recurrent exacerbations.

temporary recovery has taken place there is a tendency for subsequent attacks to occur. There is also a tendency to hæmatoporphyrinuria during the exacerbations.

Finally, it may be emphasized that although it is often stated that many skin diseases may be associated with eosinophilia, as a matter of fact few skin diseases other than the bullous dermatoses produce any marked degree of eosinophilia, so that a differential leucocyte count may afford valuable diagnostic evidence. The absence of eosinophilia by no means excludes pemphigus or erythema bullosum or any other bullous dermatosis, but the presence of eosinophilia in a doubtful case increases the probability of the condition being one of these: it is noteworthy that whereas eosinophil cells may abound in the contents of the natural bullæ, those which occur in a blister produced artificially in the same case present no such eosinophilia.

Herbert French.

BUZZING IN THE EARS.—(See TINNITUS, p. 877.)

CACHEXIA literally means 'a bad habit,' and is an ill-defined term used to include almost any depraved condition of the body in which nutrition everywhere is defective. It is generally applied to patients who exhibit change of complexion in the direction of sallowness or actual anæmia in association with progressive loss of weight; but actual weight-loss is not essential, for in *cachexia strumipriva*, or myxœdema, there is nearly always considerable increase in bulk and weight together with debility, anæmia, and general ill health. The word is generally prefixed by a qualifying adjective, such as *cancerous*, *sypilitic*, *malarial*, *tuberculous*, or *tropical*, the diagnosis being indicated by other symptoms or by the history. In many cases the cause is an ill-defined microbial-toxic state of affairs, such as that which is so apt to accompany *pyorrhœa alveolaris*, *intestinal stasis*, *chronic pyelonephritis*, *coli bacilluria*, chronically inflamed tonsils and adenoids, *bronchiectasis*; and it may be associated with other microbial-toxic lesions such as *rheumatoid*

arthritis. Other varieties of cachexia that may be given special mention, and which, if they are borne in mind, are not as a rule difficult of diagnosis, are *C. splenica*, including blood diseases such as leucocythemia, in which with progressive loss of weight and anemia there is enlargement of the SPLEEN (p. 774); *C. uterina*, from chronic non-fatal lesions of the uterus or other pelvic organs, notably leucorrhœa, chronic endometritis, or fibroid tumours, and often accompanied by brown disfiguring pigmentation (chloasma uterinum), especially on the forehead and round the eyes; *C. parasitica*, due to infection by the more serious intestinal or other parasites, especially *Ankylostomum duodenale*, *Bothriocephalus latus*, *Bilharzia hæmatobia*, and *Trichina spiralis*; *C. chlorotica*, a synonym for chlorosis; *C. mercurialis*, attributed to the effects of mercury, though perhaps really due to the syphilis for which the mercury has been given; *C. exophthalmica*, sometimes associated with Graves' disease; *C. palustris*, or marsh cachexia, due either to actual malaria or to constant living in unhealthy, damp surroundings; *C. alkalina*, the bad health caused by taking large quantities of alkalis for a long period, and evidenced by pallor, breathlessness, emaciation, and anemia; *C. aquosa*, also called *pica* and *C. africana*, a term given to an anæmic condition leading to serous effusion, and often accompanied by perversion of appetite, seen in hot climates and especially among negroes; it has received many names, such as white tongue, stomach disease of negroes, negro cachexy, intratropical anemia, dirt-eating disease; doubtless many different disorders have been included under this name, including the results of malaria or of intestinal worms; *C. renal*, which results from prolonged albuminuria, especially in subacute tubal nephritis; *C. scorbutica*, a condition formerly described as associated with rickets, though more likely related to the infantile scurvy of Barlow, nutrition being impaired, the head and upper part of the body perspiring profusely during sleep, anemia developing, and the patient being intolerant of bedclothes owing to tenderness or actual painfulness of the bones from subperiosteal hæmorrhages; there may or may not be bleeding gums; *C. saturnina*, from chronic lead poisoning (p. 45). Chronic starvation, bad habits, late hours, excessive cigarette smoking, and unhealthy occupations are amongst the causes of simple cachexia. *Herbert French.*

CACOGGEUSTIA. (See TASTE, ABNORMALITIES OF, p. 859.)

CAMMIDGE'S PANCREATIC REACTION. The results of long clinical experience and animal experiments demonstrate that a positive 'pancreatic' reaction is strong presumptive evidence of defective carbohydrate metabolism arising from deficiency of the internal secretion of the pancreas, particularly when a pronounced reaction is obtained with the fasting urine. When the urine of a patient exhibiting other evidence of pancreatic disease gives a positive result, a diagnosis of acute or chronic pancreatitis is indicated; but as functional disturbances due to other causes may give rise to similar defects of carbohydrate metabolism, a mistaken opinion may be formed if reliance is placed on the urinary analysis alone. The pancreatic reaction is not pathognomonic of pancreatitis; the results of the test need to be considered in conjunction with the clinical symptoms and the evidence to be obtained by complete analysis of the urine, blood, and feces; for then one can not only obtain confirmation of the indications given by the urine examination, but also infer the probable cause of the changes in the pancreas—a most important point—for pancreatitis is rarely, if ever, a primary disorder, but is usually secondary to a catarrh of the duodenum, gall-stones in the common bile-duct or ampulla of Vater, invasion of the pancreas by a duodenal or gastric ulcer, malignant disease, either primary in the pancreas or secondary to some other organ, back pressure from disease of the heart or lungs, arteriosclerosis, alcoholism and cirrhosis of the liver, syphilis, tubercle, influenza, typhoid fever, mumps, etc. In many of these the clinical signs and symptoms alone are sufficient to indicate the cause of the pancreatitis, but in others they are so indefinite or obscure that it is only by considering the results of a complete quantitative and qualitative analysis of the urine, blood, and feces that a correct diagnosis can be reached.

A negative pancreatic reaction does not exclude chronic pancreatitis, or rather the changes produced by inflammation of the gland, for the reaction is only obtained when the formation of the internal secretion is insufficient to carry out the carbohydrate metabolism in a normal manner; sclerosis of the pancreas due to past inflammation does not, therefore, necessarily cause a reaction after the inflammation has subsided. Cancer of

the pancreas, too, is associated with a positive reaction in only about 25 per cent of cases, the presence of the growth apparently not preventing an adequate formation of the internal secretion of the gland in the remaining 75 per cent.

The pancreatic reaction depends upon the fact that the urine of patients suffering from pancreatic inflammation contains dextrin-like bodies, which, when hydrolysed by boiling the urine with dilute HCl, yield a pentose that may be recognized by converting it into an osazone by treatment with phenylhydrazine. The golden yellow flocculent deposit of hair-like crystals produced in this way is very characteristic when examined with the microscope, but as glycuronic acid, which is set free in many urines during the hydrolytic process, also gives a crystalline compound with phenylhydrazine, it is removed by treating the still acid urine with tribasic lead acetate after the excess of HCl has been neutralized with lead carbonate. In order to obtain a clean result, the lead which goes into solution is removed by converting it into an insoluble sulphate or sulphide, and filtering, before the phenylhydrazine test is applied.

A more reliable method of carrying out the test, which gives quantitative results by which one case may be compared with another or the effects of treatment may be followed, is to determine the 'difference value' of the urine, that is to say, the difference between the reducing power of the urine before and after hydrolysis with dilute HCl, suitable precautions being taken to exclude glycuronic acid, etc., prior to the determination being made. Normal urines gives no difference value; in cases of pancreatitis readings of 20 to 60 units per cent. with a total of 100 to 500 units, are usually obtained.

These methods cannot be applied satisfactorily to urines containing sugar, and, for such, a modification has been devised in which a hydrochloric acid solution of the precipitated lead salt from the basic lead acetate solution is submitted to steam distillation. The quantity of furfuraldehyde formed is determined by treating the distillate with sodium bisulphite and then titrating with a

standardized solution of iodine. Numerous experiments have shown that the 'iodine coefficient' of normal urines is nil, and that one unit by this method corresponds to three units on the difference value scale, so that when there is inflammation of the pancreas the iodine coefficient rises to 20 or more per cent, with a total for the twenty-four hours' urine of 100, 200, or over. Cases with simple digestive and hepatic disturbances may give a slight iodine coefficient, but it rarely exceeds 1.0 to 1.5 per cent. Many cases of cancer of the pancreas give a negative iodine coefficient and difference value, but in some 25 per cent similar readings to those found in cases of simple pancreatitis are obtained.

Other points to be noticed in examining the urine in suspected cases of pancreatic disease are :

1. The presence of calcium oxalate crystals (see OXALURIA, p. 523) in the centrifugized deposit : these are met with in 63 per cent of cases of chronic pancreatitis, or 73 per cent if jaundiced cases are excluded.
2. A pathological excess of urobilin (*Fig. 322*, p. 406) ; this is a very constant indication of cholangitis, and a particularly useful sign of gall-stones in the common bile-duct, whether accompanied by jaundice or not.
3. A well-marked indican reaction : pointing to a catarrhal condition of the intestinal mucous membrane, with abnormal putrefactive changes in the contents of the intestine.
4. Bile pigment in the urine : showing that there is some obstruction to the free flow of bile into the intestine, due to impacted gall-stones, gripping of the common bile-

Days 113, 114. Charts to illustrate the difference blood-sugar values between the normal and a case of chronic pancreatitis. S, Sugar, mg/ml, per cent. D, Difference value, mg/ml, per cent. 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100, 101, 102, 103, 104, 105, 106, 107, 108, 109, 110, 111, 112, 113, 114, 115, 116, 117, 118, 119, 120, 121, 122, 123, 124, 125, 126, 127, 128, 129, 130, 131, 132, 133, 134, 135, 136, 137, 138, 139, 140, 141, 142, 143, 144, 145, 146, 147, 148, 149, 150, 151, 152, 153, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163, 164, 165, 166, 167, 168, 169, 170, 171, 172, 173, 174, 175, 176, 177, 178, 179, 180, 181, 182, 183, 184, 185, 186, 187, 188, 189, 190, 191, 192, 193, 194, 195, 196, 197, 198, 199, 200, 201, 202, 203, 204, 205, 206, 207, 208, 209, 210, 211, 212, 213, 214, 215, 216, 217, 218, 219, 220, 221, 222, 223, 224, 225, 226, 227, 228, 229, 230, 231, 232, 233, 234, 235, 236, 237, 238, 239, 240, 241, 242, 243, 244, 245, 246, 247, 248, 249, 250, 251, 252, 253, 254, 255, 256, 257, 258, 259, 260, 261, 262, 263, 264, 265, 266, 267, 268, 269, 270, 271, 272, 273, 274, 275, 276, 277, 278, 279, 280, 281, 282, 283, 284, 285, 286, 287, 288, 289, 290, 291, 292, 293, 294, 295, 296, 297, 298, 299, 300, 301, 302, 303, 304, 305, 306, 307, 308, 309, 310, 311, 312, 313, 314, 315, 316, 317, 318, 319, 320, 321, 322, 323, 324, 325, 326, 327, 328, 329, 330, 331, 332, 333, 334, 335, 336, 337, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347, 348, 349, 350, 351, 352, 353, 354, 355, 356, 357, 358, 359, 360, 361, 362, 363, 364, 365, 366, 367, 368, 369, 370, 371, 372, 373, 374, 375, 376, 377, 378, 379, 380, 381, 382, 383, 384, 385, 386, 387, 388, 389, 390, 391, 392, 393, 394, 395, 396, 397, 398, 399, 400, 401, 402, 403, 404, 405, 406, 407, 408, 409, 410, 411, 412, 413, 414, 415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433, 434, 435, 436, 437, 438, 439, 440, 441, 442, 443, 444, 445, 446, 447, 448, 449, 450, 451, 452, 453, 454, 455, 456, 457, 458, 459, 460, 461, 462, 463, 464, 465, 466, 467, 468, 469, 470, 471, 472, 473, 474, 475, 476, 477, 478, 479, 480, 481, 482, 483, 484, 485, 486, 487, 488, 489, 490, 491, 492, 493, 494, 495, 496, 497, 498, 499, 500, 501, 502, 503, 504, 505, 506, 507, 508, 509, 510, 511, 512, 513, 514, 515, 516, 517, 518, 519, 520, 521, 522, 523, 524, 525, 526, 527, 528, 529, 530, 531, 532, 533, 534, 535, 536, 537, 538, 539, 540, 541, 542, 543, 544, 545, 546, 547, 548, 549, 550, 551, 552, 553, 554, 555, 556, 557, 558, 559, 560, 561, 562, 563, 564, 565, 566, 567, 568, 569, 570, 571, 572, 573, 574, 575, 576, 577, 578, 579, 580, 581, 582, 583, 584, 585, 586, 587, 588, 589, 590, 591, 592, 593, 594, 595, 596, 597, 598, 599, 600, 601, 602, 603, 604, 605, 606, 607, 608, 609, 610, 611, 612, 613, 614, 615, 616, 617, 618, 619, 620, 621, 622, 623, 624, 625, 626, 627, 628, 629, 630, 631, 632, 633, 634, 635, 636, 637, 638, 639, 640, 641, 642, 643, 644, 645, 646, 647, 648, 649, 650, 651, 652, 653, 654, 655, 656, 657, 658, 659, 660, 661, 662, 663, 664, 665, 666, 667, 668, 669, 670, 671, 672, 673, 674, 675, 676, 677, 678, 679, 680, 681, 682, 683, 684, 685, 686, 687, 688, 689, 690, 691, 692, 693, 694, 695, 696, 697, 698, 699, 700, 701, 702, 703, 704, 705, 706, 707, 708, 709, 710, 711, 712, 713, 714, 715, 716, 717, 718, 719, 720, 721, 722, 723, 724, 725, 726, 727, 728, 729, 730, 731, 732, 733, 734, 735, 736, 737, 738, 739, 740, 741, 742, 743, 744, 745, 746, 747, 748, 749, 750, 751, 752, 753, 754, 755, 756, 757, 758, 759, 760, 761, 762, 763, 764, 765, 766, 767, 768, 769, 770, 771, 772, 773, 774, 775, 776, 777, 778, 779, 780, 781, 782, 783, 784, 785, 786, 787, 788, 789, 790, 791, 792, 793, 794, 795, 796, 797, 798, 799, 800, 801, 802, 803, 804, 805, 806, 807, 808, 809, 810, 811, 812, 813, 814, 815, 816, 817, 818, 819, 820, 821, 822, 823, 824, 825, 826, 827, 828, 829,

duct by the inflamed head of the pancreas, which surrounds the duct in 62 per cent of cases, malignant disease of the head of the pancreas, or a growth in the common bile-duct.

Examination of the blood gives even more reliable indications of disturbances of carbohydrate metabolism due to deficiency of the internal secretion of the pancreas than does analysis of the urine. When samples of blood are taken from a finger-prick in the morning, fasting, and at hourly intervals after breakfast for 4 to 5 hours, the percentage of sugar rises for the first 2 or 3 hours following the meal and then gradually drops back to the fasting level in a normal person, while the difference value never exceeds about 0.004 to 0.005 per cent (*Fig. 113*): but when a similar series of analyses is carried out with the blood of a patient suffering from insufficiency of the internal secretion of the pancreas very different results are obtained. Unless the patient is a diabetic, the blood-sugar curve follows the usual course, but the fasting difference value is always higher than normal, ranging from 0.050 to 0.150 per cent in the cases coming under the writer's observation; after the meal it sinks as the percentage of sugar rises, and increases again as the blood-sugar falls, so that when the respective values are plotted out in a graph the sugar curve and the difference value curve move in opposite directions (*Fig. 114*). This relationship appears to be characteristic of deficiency of the internal secretion of the pancreas, and is constantly found in cases where there is active inflammation of the gland, or where sclerotic changes of sufficient extent to impair its functional efficiency have occurred.

For the purposes of further differential diagnosis the results of a qualitative and quantitative analysis of the faeces are most important. In carrying out the analysis the points to be noticed particularly are:—

1. The presence or absence of stercobilin: in gall-stone obstruction, traces at least are nearly always met with, whereas in malignant disease of the head of the pancreas total blocking of the duct is the rule, although the soft growths occurring primarily in the common duct usually allow some bile to filter through so that traces of stercobilin are met with in the faeces.

2. A positive reaction for biliverdin: this indicates excessively active peristalsis in the upper intestine, with catarrh of the walls, and when associated with the presence of occult blood is suggestive of duodenal ulcer.

3. The percentage of unabsorbed fat: in cancer of the pancreas this is always very high, 70 to 80 per cent: it is usually somewhat less in growths of the common duct, averaging 60 to 70 per cent, and varies from a subnormal percentage in early catarrh of the pancreas to as much as 50 or, rarely, even 80 per cent in advanced chronic pancreatitis.

4. More important still, however, is the relation of the 'unsaponified' to the 'saponified' fats, for whereas the former are in excess in diseases that interfere with the digestive functions of the pancreas, such as cancer of the gland and advanced chronic pancreatitis, the latter predominate in obstruction of the common duct by gall-stones without pancreatitis, and in malignant growths not involving the pancreas. It must be borne in mind, however, that owing to the abnormal activity of fat-splitting bacteria in the lower bowel, such as is met with in some cases of intestinal catarrh, an excess of saponified fat may be found in cases of chronic pancreatitis where the disease is due to an infection spreading from the duodenum. A similar excess is often met with in early catarrhal pancreatitis, owing probably to an increased flow of pancreatic juice analogous to the salivation met with in parotitis.

5. Microscopical examination of the faeces for fat globules, fatty acid crystals, undigested muscle fibres, and connective tissue should not be omitted: a large excess of fat globules and free fatty acid crystals, with numerous isolated undigested muscle-fibres, point to cancer of the pancreas or advanced cirrhosis of the gland, whereas muscle associated with connective tissue points to defective gastric digestion.

6. An acid reaction of the fresh stool is in favour of a diagnosis of pancreatic disease: in simple gall-stone obstruction the faeces are usually alkaline.

7. Occult blood, when constantly present in the faeces (see p. 104), is suggestive of malignant or, more rarely, advanced pancreatitis, in which it is now well known that there is a hamorrhagic tendency; while the discovery of blood intermittently points to a gastric or duodenal ulcer, which may be invading the pancreas and setting up pancreatitis.

By carefully considering all the facts thus obtained, and interpreting them in the light of the clinical signs and symptoms, it is possible, not only to diagnose correctly the

existence of disease of the pancreas, but also to arrive at a satisfactory conclusion as to its probable cause. Affection of the pancreas is much commoner than is generally supposed, and many trying cases of chronic indigestion, recurring or persistent jaundice, and obscure affections of the upper abdomen would be explained, and satisfactorily treated, if investigated as above. Undiagnosed and consequently untreated pancreatitis is probably the most common cause of diabetes. If this were more widely recognized, much might be done to stay the further increase of that disease. *P. J. Cammidge.*

CEPHALALGIA. (See HEADACHE, p. 369.)

CHARCOT-LEYDEN CRYSTALS were at one time supposed to consist of spermin, but now there is considerable doubt as to their exact chemical nature. Their chief importance from a clinical point of view is that they are more common in certain conditions than in others. They may be found in the sputum, the blood, or the stools. They need the high power of the microscope for their detection. Each resembles an elongated diamond with clear-cut edges without colour, but with a slightly yellow appearance when seen obliquely. They stain with eosin, and are soluble in hot water, in mineral acids, and in alkalis, so that for their detection a fresh specimen is required.

In the *sputum* they are commoner in *asthma* than under any other circumstances—true spasmodic asthma, such as also gives rise to CURSCHMANN'S SPIRALS (p. 191), and eosinophil corpuscles in the sputum. In determining whether a given case is one of paroxysmal dyspnoea, cough, or bronchitis on the one hand, or true asthma complicated by bronchitis upon the other, numbers of Charcot-Leyden crystals in a fresh specimen of sputum are evidence in favour of the latter. Small numbers of the crystals may be found in *bronchitis* and in association with *bronchiectasis*, but in true asthma their numbers may be quite large.

The occurrence of Charcot-Leyden crystals in the *blood* is of little diagnostic value. They are seldom found in fresh blood; but when the latter has stood for some time in bulk they develop, particularly in *leukamia*. Some have tried to draw important clinical deductions from the development of these crystals in blood, but it is doubtful whether they really have any significance of value.

Charcot-Leyden crystals have been found in the *stools* in a great variety of diseases, but whether or not clinical deductions can be drawn from their presence is doubtful. It is stated that, when they abound, the patient is probably suffering from an *animal parasite*; but it affords no indication of the nature of the parasite present. Their occurrence should lead one to examine the feces for parasites or their ova with even greater care than usual.

Herbert French.

CHELOID. A cheloid is a new growth of fibrous tissue in a scar. Although a spontaneous variety is described, it is probable that there has always been some preceding trauma of the skin producing scar tissue, such as that left by chicken-pox, an acne pustule, or a slight wound, perhaps caused by the wearing of a pendant or a bracelet, which has been forgotten or unnoticed by the patient. In ordinary cases cheloid occurs in obvious scar tissue such as that of a burn or scald, a vaccination scar, an operation wound, or in scars following abscesses or other traumata of the skin, especially when healing has been delayed. The new cicatricial tissue, instead of contracting, takes on a new activity and forms a raised, flat, rather tough tumour of a pinkish colour, which spreads at the edge by claw-like processes and is often attended by severe pain. It is distinguished by these from an ordinary hypertrophic scar, which has no processes and does not spread beyond the margins of the original cicatrix. The other condition likely to be mistaken for cheloid is morphea. This can generally be distinguished by its smooth, flat surface, ivory colour, and regular outline. The so-called acne cheloid, or dermatitis papillaris capillitii, in which small projections of fibrous tissue occur on the back of the neck, is not a cheloid in the proper sense of the term.

Ernest Dore.

CHEST, BLOODY EFFUSION IN.—When, on needling a pleural cavity containing fluid, this fluid is found to be obviously blood-stained, the fact is suggestive of one of three things: that the pleurisy has been exceedingly acute; that the chest has already been tapped not long previously, so that there has been hemorrhage into the residual fluid; or that there is malignant disease involving the pleura.

The history of the case may at once indicate that the inflammation has been very acute, the symptoms being of short duration, with much pyrexia, the exudate highly albuminous, of high specific gravity, coagulating spontaneously, and microscopically exhibiting numerous polymorphonuclear cells and lymphocytes, abundant red corpuscles, but no particles of growth in the centrifugalized deposit.

If blood is found in pleuritic fluid at a second tapping when it was not present at the first, the fact by itself is of little value in differential diagnosis, for the bleeding has probably been caused by the act of paracentesis.

When there is a new growth, and the effusion contains obvious blood at a first tapping, it is likely that the symptoms have been of gradual onset, without marked pyrexia. By no means every case of malignant disease affecting the pleura produces a blood-stained

effusion: but when the effusion is blood-stained at a first tapping in a case that has not run a very acute course one should be suspicious of new growth, and an early opportunity should be taken to have the thorax X-rayed. The abnormal shadows revealed (*Fig. 120*, p. 136; *Fig. 105*, p. 114) may give the diagnosis of new growth very much earlier than is feasible by any other means, though sometimes the nature of the case has been cleared up by finding large neoplastic cells or even particles of new growth in the centrifugalized deposit from the fluid itself. In not a few cases there have also been comparatively large numbers of coarsely granular eosinophil corpuscles in the effusion at the same time, and such eosinophilia in a pleural exudate is suggestive of new growth. Without a skiagram it is often impossible to be sure of the diagnosis until the progress of the case has been watched, sometimes for weeks: pleural effusion, like that of a simple case, may be the only sign for a long time, but sooner or later one will expect to find evidence of obstruction to a bronchus or to the superior vena cava as the growth spreads: or alternatively a primary growth, at first unsuspected or not found, may be discovered elsewhere, for instance in connection with a bone, the rectum, pelvic organs, thyroid gland, and

Fig. 115. Skiagram showing an interlobar empyema of small size. There were no abnormal physical signs at the time the skiagram was taken, but subsequently the empyema was found by needling through the third right intercostal space in front, and it was opened and cured surgically.

so on. The primary growth is seldom pleural: in most cases it is primarily a lymphosarcoma of the mediastinal glands involving the pleura by direct extension. *Herbert French.*

CHEST, DEFORMITY OF.—(See DEFORMITY OF THE CHEST, p. 208.)

CHEST, PAIN IN.—(See PAIN IN THE CHEST, p. 530.)

CHEST, PUS IN.—When, on needling the chest, pus wells up into the exploring syringe, it is probable that the patient has an *empyema* (*Fig. 115*). Other lesions may simulate empyema, however, and even when empyema is actually present it is important not to let the diagnosis rest at that; but rather to regard it as a symptom and try to diagnose

its cause. It by no means follows, of course, that when the exploring syringe fails to detect pus, an empyema is not present, for sometimes it is situated either between the lower lobe and the diaphragm, in front of the lung or between the lobes, or in some other position in which it is difficult to hit it off with the needle. When pus is found but the amount is only quite small, there may be some doubt as to whether it came from an empyema outside the lung, from a bronchus, or an *abscess cavity in the lung substance*. The nature of the case may remain undecided until a subsequent puncture, or a resection of a rib, conclusively discovers intrapleural pus. Even when pus wells up in the exploring syringe, it is possible to mistake for empyema a collection of pus which is below the diaphragm. A *subdiaphragmatic abscess* (Fig. 116) and an *abscess within the liver* are the two conditions most liable to simulate empyema in this way. If, however, the history, the symptoms, and the physical signs do not serve to

Fig. 116.—Stereogram showing the appearance in a case of subdiaphragmatic abscess on the right side. The right emphora of the diaphragm is pushed up, and the costophrenic angle is not obliterated as it would be if the pus had been above the diaphragm. The diagnosis was confirmed by operation. (Fig. 116, J. M. Woodburn, Morrison.)

Fig. 117. Early phthisis, showing only a slight degree of mottled opacity at the apex of the right lung, the rest being clear. The sputum contained tubercle bacilli.

distinguish between these different conditions, it will generally be necessary to evacuate the pus, and the surgeon's finger inserted through the wound will be able to feel whether the diaphragm is above or below the collection. Even then there is one possible source of error—namely, when there is pus both above and below the diaphragm. A subdiaphragmatic abscess, secondary perhaps to appendicitis upon the right side, or to a leaking gastric ulcer upon the left, may have infected the pleura through the diaphragm, causing first a serous and then a purulent effusion, separated from that below the diaphragm merely by the thickness of that muscle. It may be very difficult indeed to be sure of this condition, even at the time of operation, the nature of the case not being fully cleared up until, when one of the pus-containing cavities has been

evacuated, the abnormal physical signs persist, and a second collection of pus, above or below the diaphragm as the case may be, is found at a subsequent exploration. The X rays may be of considerable assistance sometimes in showing whether the diaphragm is above the pus or below it, though a screen examination is better than a skiagram sometimes, because the up-and-down movement which may be visible on the screen may help to define the situation of the diaphragm in a way which is lacking in a photograph.

If the physical signs, symptoms, and the result of needling, all prove conclusively that the chest contains an empyema, it is still necessary to decide as far as possible the nature of the latter. Its commonest cause is pneumococcal infection, nearly always preceded by lobar pneumonia in adults, in children sometimes by bronchopneumonia, but not infrequently arising insidiously. It is probable that many of the so-called latent empyemata of children have really been preceded by undiagnosed bronchopneumonia. Difficulty often arises from the fact that the amount of pus present is not great, so that though it compresses the lung sufficiently to render the alveoli airless, the bronchial tubes still remain patent, and there is no complete dullness at the base or wherever the empyema may be; and over the affected area there may be bronchial breathing and crackling râles, instead of the absence of breath-sounds and of voice-sounds that usually accompanies empyema in adults. If there is doubt as to the nature of the empyema as judged by the history, bacteriological examination of the pus will often indicate its origin. The commonest organisms to be found are pneumococci, streptococci, and staphylococci, though *Bacillus coli communis*, typhoid bacilli, Pfeiffer's influenza bacilli, Friedländer's pneumobacilli, and the *Bacillus pyocyaneus* also occur, and even other organisms, such as those of gaseous gangrene, may be present in some instances. The mode of infection

Fig. 118. Skiagram of a chest exhibiting extensive phthisis: the clarity at the right apex is due to a large cavity here; below this cavity there is extensive mottled opacity; and in the left lung nearly two-thirds are mottled and opaque, only the basal third exhibiting real clarity; the diaphragm on each side lacks its normal rounded contour, and the heart shadow is less clear than it should be because of adhesions around that organ. (By Dr. Cobbrell.)

generally either via the lung, or beneath the diaphragm; and careful inquiry into the history and symptoms will generally indicate

which of these two paths has been the more likely. When infection from any peritoneal condition such as appendicitis, leaking gastric or duodenal ulcer, infected gall-bladder, or subdiaphragmatic, perinephric, or hepatic abscess, can be excluded; when there has been no injury of the chest with broken rib, or a wound communicating with the exterior; and when there is nothing to indicate whether the infection has succeeded pneumonia or is itself pneumococcal, suspicion will arise that the patient has been suffering from phthisis, which has caused a pleurisy that was at first non-purulent, but which became converted into an empyema as the result of secondary infection with pyogenic organisms, especially if there is a tuberculous family history, or if the patient has himself been weakly for some time. The sputum should be examined with particular care, and X-ray examination is often helpful; for even when the compression of the lung by empyema has led to marked opacity at the base, it may still be possible to make out that apical mottling which is almost pathognomonic of phthisis (Figs. 117-119).

Rarer causes of empyema than those mentioned above, for instance a foreign body in a bronchus, epithelioma of the œsophagus or a bronchus, infected emboli causing

infarction of the lung from phlebitis, otitis media, or after child-birth, or the results of severe injury to the thorax, such as gunshot wounds or crushings causing hæmothorax and subsequent suppuration of the blood-clot, will generally have been accompanied by other symptoms, or by a history which suggests the nature of the case. *Herbert French.*

CHEST, SEROUS EFFUSION IN.—When exploratory needling of the chest discovers clear serous fluid in the pleural cavity, it is important to regard the fact merely as a symptom, for there are many different causes to which it may be due, and, whenever possible, one should decide what is the actual cause in each particular case. In the first place, the effusion may be either inflammatory or merely a transudate; the *pleuritic* must be distinguished from the *pleural* effusion. Clinical points indicating that the effusion is inflammatory rather than passive would be: its being unilateral, not bilateral and symmetrical; pyrexia; and the non-existence of the more common causes for passive effusion, particu-

larly chronic heart failure or nephritis with general anasarca. Physical, chemical, and microscopical analyses of the fluid may also serve to indicate whether the effusion is active or passive (see ASCITES, p. 59). There are cases, of course, in which there may be doubt, but it is generally easy to determine whether the effusion is due to pleurisy or not. Pleural effusions not due to pleurisy occur late, and the diagnosis will have been made already from the existence of prominent symptoms earlier in the disease, for instance, ALBUMINURIA (p. 4), DYSPNOEA (p. 246), EDEMA (p. 511), and so forth.

Pleuritic effusion, on the other hand, may be the first and most prominent symptom in the case, and it is not always easy to determine its cause. It should be an invariable rule to have the effusion examined microscopically, both for cells and for micro-organisms, and sometimes to have a guinea-pig injected with it in order to see whether in six weeks' time the inoculated animals have developed general tuberculosis. The commonest cause for apparently idiopathic pleuritic effusion is latent or undiagnosed *tuberculosis* of the lung. There may be no sputum; X-ray

Fig. 119.—Skiergram of the lungs in a case that seemed clinically to be cavity phthisis, but which has clearly been pulmonary tuberculosis of fibro-cystic type for a long time. There is marked lack of clarity of the left upper lobe, but the right lung is mottled too; old pleural adhesions are determining the right cupola of the diaphragm, and similar adhesions on the left side have drawn the heart over to the left and have pulled up the left diaphragm. Abnormal physical signs were few; simple bronchial catarrh was suspected until the roentgen was taken; at a late date, tubercle bacilli were discovered in the sputum. (By Dr. Coldwell.)

shadows may be indeterminate; there may be no abnormal apical physical signs; there may be too few bacilli for them to be detected on direct examination of the deposit, even when it has been most carefully centrifugalized; and yet inoculated guinea-pigs may develop typical tuberculosis and thus indicate the nature of the pleurisy. The time-factor in the guinea-pig test may be shortened to about a fortnight if the animal has been sensitized previously by a particular degree of X-ray treatment. When lymphocytes are the predominant cell in the centrifugalized deposit from the fluid, tubercle should always be suspected; when polymorphonuclear leucocytes are the prevailing cell, some other micro-organism, such as the pneumococcus or the streptococcus, is more probable, and it may be revealed by cultural methods.

Intrathoracic new growth, whether of the mediastinum, lung, or pleura, is fortunately uncommon, but when it occurs the symptoms and physical signs to which it gives rise

are often difficult to interpret. The growth may obstruct a bronchus and give all the physical signs of fibroid lung, with or without bronchiectasis; it may cause a big mass, bodily displacing the lungs and heart; it may cause multiple nodules which, unless they obstruct the superior vena cava and produce obvious varicose veins on the chest wall, may give rise to no very definite signs or symptoms at all; or, what is not at all infrequent, the growth may lead to pleuritic effusion which may at first seem to be simple, or even be taken to be tuberculous, growth not being suspected until the recurrence of the effusion, repeated tappings, and rapid downhill course of the disease ultimately suggest its nature. Microscopical examination of the centrifugized deposit of the pleuritic fluid sometimes leads to the detection of particles of new growth which clinch the diagnosis, whilst if the fluid in a case which is not absolutely acute is blood-stained at a first tapping, this by itself is highly suggestive of neoplasm (p. 132). The X rays often assist materially in making the diagnosis (*Fig. 120*; see also *Fig. 105*, p. 114).

Acute rheumatism is a common cause of pleurisy with effusion, particularly between the ages of five and twenty. It may occur when there have already been joint pains or other symptoms of acute rheumatism, such as chorea, recurrent tonsillitis, pericarditis, endocarditis followed by valvular disease, skin affections such as erythema multiforme,

erythema nodosum, peliosis rheumatica, or subcutaneous nodules. In such cases the diagnosis is not difficult; it is less easy when the pleuritic effusion is itself the main symptom. The youth of the patient, the absence of anaemia or of previous ill health, the absence of abnormal apical lung signs, of a family history of phthisis, the presence of a cardiac bruit, the occurrence of heart disease, acute rheumatism, or chorea in other members of the same family, the rapid onset of the disease, and the almost equally rapid resolution of the effusion, are points in favour of acute rheumatism rather than tuberculosis. When in doubt, the negative results of guinea-pig inoculation would point in the same direction, and von Pirquet's skin reaction (p. 932) would be negative. There are, however, many cases of pleuritic effusion in young people in which it is impossible to allocate the cause either to

Fig. 120. Skigram showing sarcoma of the right lung secondary to sarcoma of a kidney. The patient was a child, aged 13 years. GG, Masses of new growth. H, Heart. The lower mark G points in the direction of the lower mass of growth, but the line has not been prolonged so far as to the shadow of the growth. (*Re Dr. C. Thorsen Holland.*)

rheumatism or phthisis, and such cases are sometimes spoken of as 'simple'; doubtless most of these are either tuberculous or rheumatic, many ultimately proving to be the former.

Pneumococcal lesions of the lung generally produce pleurisy: *lobar pneumonia*, indeed, never occurs without it, though *bronchopneumonia*, even when it is pneumococcal, often does. It is also possible for pneumococcal pleuritic effusion to occur without definite lobar pneumonia or bronchopneumonia preceding it—primary pneumococcal pleurisy, the diagnosis being confirmed by the discovery of pneumococci in the fluid. It is difficult, however, to say where pneumococcal serous effusion stops and pneumococcal empyema begins, the two merging into one another, and the same case often exhibiting clear fluid at one exploration, cloudy fluid a few days later, and pus later still.

Bright's disease may cause either a passive effusion from heart failure in chronic cases, or simple accumulation of oedema fluid in the pleural cavities without heart failure in cases in which the general oedema of Bright's disease is extreme; or actual pleurisy with serous effusion, probably the result of intercurrent infection by some organism, corresponding with the peritonitis with ascites and the pericarditis that may also occur in these cases. The diagnosis will be indicated by the ALBUMINURIA (p. 4) associated with renal tubercles; and if there is bilateral effusion without universal oedema, but with the signs of heart failure in the form of orthopnoea, oedema of the legs, and perhaps ascites, the effusion is passive; it belongs to the second category if there is universal oedema; whilst if the

effusion is inflammatory it will probably be unilateral, or else more marked in one side of the chest than in the other. In a few cases an extensive pleuritic effusion in a middle-aged or elderly person is the first indication that there is anything renal the matter, the diagnosis of red granular contracted kidney being confirmed by the urinary changes, big heart, ringing aortic second sound, high blood-pressure, or by albuminuric retinitis.

Any of the severe blood diseases, particularly *Hodgkin's disease*, *lymphadenoma*, *leukæmia*, *splenic anæmia*, *pseudoleukæmia infantum*, and to a less extent *pernicious anæmia*, may give rise to inflammation of any of the serous membranes, and thus lead to ascites, pericarditis, or pleurisy with effusion. The latter is seldom an early symptom in such cases, however, and the diagnosis will generally be known already from the presence of pronounced ANÆMIA (p. 25), ENLARGEMENT OF THE LYMPHATIC GLANDS (p. 471), or ENLARGEMENT OF THE SPLEEN (p. 774), with or without pathognomonic blood-changes already discussed under these various headings.

Syphilis is not a common cause of pleural effusion, but it is the basic factor in some cases, especially of the recurrent and apparently idiopathic type. The effusion develops, as a rule, as a late tertiary phenomenon, in middle age or later; and it is often associated with syphilitic gummatosis or fibrosis of the mediastinum, with obstruction of the superior vena cava resulting in varicosity of the veins of the chest wall, and other phenomena which might point more readily to growth than to syphilis. The prolonged course of the case may be the only way of distinguishing the diagnosis; for even if the patient's Wassermann reaction is strongly positive it does not follow that such intrathoracic troubles as he has may not be sarcomatous instead of syphilitic. The X rays will not differentiate between the two, unless perhaps the shadows found at a first examination are seen to have lessened appreciably after a course of antisyphilitic treatment.

Pleuritic effusion may sometimes be secondary to *infection of the pleura from inflammatory changes below the diaphragm*; thus *appendicitis* may lead to micro-organisms tracking up behind the ascending colon to reach the diaphragm, there perhaps producing a small subdiaphragmatic abscess, or a local inflammation which, stopping short of pus formation, ultimately subsides. The bacteria in contact with the lower surface of the diaphragm can pass through the latter and infect the pleura without there being actual perforation of the diaphragm; it is noteworthy that passage of micro-organisms in the reverse direction is so rare as to be almost negligible; acute peritonitis often produces acute pleurisy, but the latter, or even empyema, seldom produces peritonitis. Any inflammatory mischief below the diaphragm may lead to dry pleurisy, pleuritic effusion, or empyema. One need not enumerate all such cases, but they should be borne in mind as possibilities. There may have been acute general peritonitis, or a more local inflammation of the peritoneum tracking in the manner already described in connection with appendicitis. This is possible when there is leaking from a gastric or duodenal ulcer; local infection from the gall-bladder; pyosalpinx; pelvic peritonitis due to whatever cause; perinephric inflammation secondary to renal calculus or injury, acute ascending nephritis, tuberculosis of the kidney, coli bacilluria, pyelitis; hepatic abscess or other inflammatory changes in or about the liver, such as infective cholangitis, suppurative pylephlebitis, or the softening and breaking down of new growth, gumma, or hydatid cyst. When the possibility of a pleuritic effusion being secondary to an abdominal lesion of some kind is borne in mind, the diagnosis of the case is generally indicated, at least approximately, by the preceding history and symptoms. If the fluid obtained smells as though it were infected with *Bacillus coli communis*, it is an additional argument in favour of some subdiaphragmatic cause.

Infarction of the lung, whether thrombotic or embolic, is apt to cause dry pleurisy; but if the infarct has been extensive, or is due to embolism from some septic source such as a lateral sinus or jugular vein thrombosis in connection with otitis media, or other similar lesions causing venous clotting, the inflammation of the pleura tends to go further and produce an effusion which, at first serous, may later become purulent. The diagnosis is sometimes obvious; but when after an operation, perhaps for excision of an inflamed appendix, the patient a few days later develops pleurisy with effusion it may not occur to one that a possible explanation of the trouble is that a vein in the region of the right iliac fossa has become inflamed and thrombosed, and that portions of the clot have been detached and carried to the lung, where multiple infected emboli have led to pleurisy and serous effusion, without going so far as to produce either abscess in the lungs or empyema.

Should hæmoptysis occur in such cases, as it sometimes does, phthisis may be feared ; but it will be excluded by the absence of tubercle bacilli on repeated examination of the sputum.

Occasionally the fluid obtained on needling the chest is distinctly *chylous*, in which case the first suspicion is that there has been some interference with the thoracic duct, either by *injury* or by an *intrathoracic new growth*. Sometimes, however, this rare symptom is due to remoter causes, such as *chronic nephritis* or *leukæmia*, just as these may occasionally produce chylous ascites (see p. 72), or *lipæmia* : in a few instances a chylous effusion into the chest has cleared up after tapping, no ascertainable cause being found.

Cholesterol crystals have been found in some cases of pleuritic effusion, their presence being suggested immediately when the fluid presents a scintillating 'gold paint' appearance : the crystals are recognizable at once under the microscope (*Fig. 263*, p. 317). The occurrence of 'gold paint' effusion is not distinctive of any one cause, for the crystals have been found in tuberculous, staphylococcal, neoplastic, and other effusions indiscriminately, just as in the case of corresponding 'gold paint' pericardial effusions. They appear to result from secondary chemical changes in the fluid apart from its primary cause.

Multiple serositis or polyorrhomenitis is a term used to express any condition in which there is recurrent inflammation and serous effusion into more than one serous membrane. It generally affects the peritoneum, pericardium, and both pleurae either simultaneously or successively. It is not a disease in itself, so that the differential diagnosis of the cause of the combined effusions has to be made upon the same lines as that described for each separately. There are cases in which, even when the patient dies, the precise nature of the multiple serous inflammations and effusions is obscure ; it is very possible that the original microbial cause has disappeared, leaving behind it so much fibrotic thickening of the membranes that even the normal secretions are unable to drain away as fast as they should, with the result that recurrent tapping at comparatively short intervals becomes necessary, the patient ultimately dying of exhaustion, nothing being found post mortem except fibrous thickening of the peritoneum, pericardium, and pleurae, with more or less extensive perihepatitis, perisplenitis, adherent pericardium, and chronic mediastinitis. The general opinion is that the primary cause in these cases has been acute rheumatism, tuberculosis, or syphilis. Sometimes secondary malignant disease affects more than one of the serous membranes at the same time and produces a clinical picture which at first simulates chronic simple polyorrhomenitis : there are generally symptoms due to the primary growth, but occasionally, especially in connection with diffuse carcinoma of the stomach—'indiarubber-bottle' stomach—the primary growth causes no symptoms, and the nature of the multiple serous effusions may be obscure unless particles of new growth can be detected in the centrifugized deposit, or secondary masses can be found in the liver or lymphatic glands, such as the left supraclavicular (*Fig. 77*, p. 66). Sometimes the diagnosis is not arrived at until a post-mortem examination is made.

Besides chronic tuberculous, rheumatic, syphilitic, and malignant polyorrhomenitis, a similar condition may be due to Bright's disease or any of the severe anæmias ; the differential diagnosis of the serous effusions to which these may give rise has been discussed above. Careful examination of the blood and urine, together with estimation of the blood-pressure, examination of the optic discs, and routine physical examination of the various body systems, are essential before the correct diagnosis can be arrived at. *Herbert French.*

CHEST, VARICOSE VEINS ON.—(See VEINS, VARICOSE THORACIC, p. 910.)

CHEYNE-STOKES RESPIRATION, or periodic breathing, consists in the occurrence of a series of inspirations, beginning with a hardly perceptible movement, increasing to a maximum, and then declining in force and length until they cease in a period of apnoea of some seconds' duration, during which the patient may appear to be dead, but at the end of which a low inspiration, followed by one more decided, and then others of increasing depth, mark the beginning of a new ascending series of inspirations, which in their turn, when the maximum has been reached, become progressively smaller again, to end in another period of apnoea ; and so on with more or less periodicity (*Fig. 121*). The duration of each period varies from half a minute to two minutes or even more. There is a peculiar variety of periodic breathing in which, instead of a waxing and waning sequence, only two or perhaps

three rapid deep breaths are made at a time, with long periods of apnoea between them—a variety of periodic breathing which is sometimes spoken of as Biot's.

Periodic breathing may occur during sleep in the very young and in the very old without there being actual disease. Cheyne-Stokes breathing in persons who are awake is generally a late phenomenon, having been preceded by other symptoms, particularly uræmic or cardiac; but in cases of progressive softening of the medulla oblongata secondary to

FIG. 121. Cheyne-Stokes breathing. A graphic record from a case of arterial degeneration and softening of the medulla oblongata. The two curves were completed in 143 seconds.

arterial degeneration it may be an early and salient symptom: seldom is it purely functional, though there are instances in which the ordinary breathing of the individual has been of Cheyne-Stokes type for so long, without any further evidence of disease developing, that one is compelled to attribute the phenomenon to purely functional causes. Broadly speaking, one may classify the chief causes of periodic breathing as follows:—

1. Arterial, especially with Degenerative Changes in the Medulla Oblongata:—

Arteriosclerosis, with or without granular kidney
Senile degeneration
Syphilis.

2. Uræmic, in cases of:

Acute nephritis
Chronic nephritis
Calculus disease of the kidney

Tuberculous kidney
Ascending nephritis, acute or chronic

Cystic kidneys
Carcinoma of the kidney
Sarcoma of the kidney.

3. Chronic Heart Failure:—

Secondary to valvular heart disease
Secondary to myocardial degeneration, especially fatty or fibroid heart

Secondary to chronic obstruction in the lungs, especially from emphysema and bronchitis, or fibroid lung
Associated with very high systemic blood-pressure.

4. Narcotic Poisoning, especially from:—

Morphia
Opium

Chloral
Butyl chloral hydrate

Veronal
Sulphonal.

5. Macroscopic Lesions of the Brain or its Coverings:—

Meningitis, tuberculous, suppurative, posterior basal, cerebrospinal
Hydrocephalus
Tumour of the brain, especially of the pons or medulla

Hæmorrhage
Softening of the brain secondary to:
Chronic arterial degeneration
Syphilis
Embolism
Caisson disease
General paralysis.

6. Acute Specific Fevers, such as:—

Pneumonia
Cholera

Diphtheria
Typhoid fever

Malaria
Infective endocarditis.

The differential diagnosis of these various conditions will be indicated by symptoms and signs other than the Cheyne-Stokes respiration, for the latter will have occurred late in the great majority of cases. The urine will be examined, the blood-pressure measured, the physical signs of the heart noted, the retina examined for retinitis, optic neuritis, or for choroidal tubercles, and careful inquiries will be made into the history. Where narcotic poisoning is suspected, the gastric contents may be recovered and analyzed, bottles found under suspicious circumstances may be examined in the same way, or evidence of hypodermic injections sought for on the patient's body or limbs. When Cheyne-Stokes respiration occurs as the main symptom in the case, the great probability is that there are degenerative changes in the medulla oblongata, nearly always secondary to arterial degeneration, either senile, syphilitic, or sclerotic. When there have been obvious symptoms of

some other kind before Cheyne-Stokes respiration develops, the latter is far more important from the prognostic than from the diagnostic standpoint. It is a sign of evil omen, though in a few cases it has persisted for many months before the end came, and in a few it has disappeared entirely for the time being, even after it had been well marked for days or weeks.

Herbert French.

CHILD-BIRTH, DIFFICULT.—(See DYSTOCIA, p. 250.)

CHILLS.—(See RIGORS, p. 736.)

CHOLURIA.—(See JAUNDICE, p. 405; and URINE, ABNORMAL COLORATION OF, p. 902.)

CHORDEE.—A condition in which, during erection, the penis, instead of remaining straight, becomes curved like a banana, either downwards or to one side. Its chief causes are gonorrhœa and injury. The differential diagnosis will depend upon the history and the existence or otherwise of a urethral discharge containing gonococci. The condition itself is due to inflammatory effusion into one corpus cavernosum, or the corpus spongiosum, as the case may be; or to blood extravasation from a burst vessel, the result of a blow, perhaps, or of fracture of the penis during resisted coitus, the diagnosis depending on the history and the break that is palpable in the penis during erection. *Herbert French.*

CHROMIDROSIS.—(See SWEATING, ABNORMALITIES OF, p. 803.)

CHYLURIA.—The passage of milky-looking urine, due to the admixture with it of emulsified fat, is known as chyluria. It is not likely to be mistaken for phosphaturia, even when the latter, especially after the largest meal of the day, causes the urine to be almost like thin milk from the spontaneous deposition of the excess of phosphates whilst the urine is still in the bladder. The opacity in the latter case disappears on the addition of a drop or two of acetic acid, whilst the fat droplets of chyluria do not clear up with acids, are obvious under the microscope, and may be brought out still more clearly by the use of special fat stains, such as osmic acid, Sudan III, or saffranin. As a rule the urine coagulates on standing, and subsequently liquefies again, when it throws up a fatty scum and deposits a sediment. The fat is most plentiful after meals which contain fat; the degree of chyluria consequently varies considerably in the same patient, and may sometimes be almost absent.

The commonest cause for the symptom is infection by *Filaria sanguinis hominis* in the tropics, adults being affected more often than children, and females more often than males. There may or may not be *elephantiasis* at the same time; the diagnosis may be suggested by eosinophilia and confirmed by the discovery of the embryos in the blood (*Fig.* 603, p. 779).

Chyluria may also occur, however, in those who have never been abroad, and it is sometimes associated in some way that is not yet fully understood with subacute prostatitis; there may be chylous ascites (p. 72) or lipemia at the same time. The diagnosis depends upon the history, the general œdema, the anaemia, cardiac hypertrophy, and upon the discovery of an abundance of albumin with renal epithelial cells and tube-casts in the centrifugalized urinary deposit, as well as fat droplets in the supernatant fluid.

Sometimes chyluria develops quite apart from any renal lesion, either spontaneously or as the result of abdominal injury; and it has generally been found in these rare cases that there has been either rupture of the receptaculum chyli, or else a blockage in the thoracic duct. The latter sometimes results in cases of malignant disease, especially carcinoma of some intra-abdominal organ with secondary deposits in the glands in the posterior mediastinum. The development of chyluria in such cases would be a late symptom, and the diagnosis would probably have been made already on account of other symptoms, especially the discovery of a primary tumour. It is important not to forget rectal and vaginal examination, lest the growth should be pelvic. *Herbert French.*

CLAW-FOOT (Pied-en-griffe) (*Fig.* 122) is much less common than CLAW-HAND, but it may arise from similar causes. The internal popliteal nerve, which supplies the interossei and lumbricals of the foot through its external plantar branch, is homologous to the ulnar nerve in the upper extremity. Its buried course in the leg does not, however, expose it to

the same chances of injury as is the case with the more superficial ulnar nerve, and consequently claw-foot is not often the result of trauma. Disease or injury of the first and second sacral segments of the spinal cord or of the corresponding spinal nerve roots may produce the characteristic deformity of the toes, in which case there would probably be disturbances of sensibility in the corresponding cutaneous areas. In acute poliomyelitis affecting those segments the diagnosis depends on the history of onset, as in the case of claw-hand of similar origin.

In *peroneal atrophy* (Tooth's paralysis) the diagnosis depends on the symmetry of the affection, the insidious way it starts, the affection of other members of the family, and the preceding or concomitant atrophy of the leg muscles, generally beginning in those supplied by the peroneal nerve (*Figs. 81, 82, p. 79*).
E. Farquhar Buzzard.

CLAW-HAND (Main-en-griffe) is the name used to describe a hand characterized by a claw-like position of the fingers (*Fig. 124*). The fingers are extended at the metacarpophalangeal joints and flexed at both interphalangeal joints. This position is the result of the over-action of the extensor communis digitorum and flexores digitorum when unopposed by the normal antagonism of the interossei and lumbricals. It is not symptomatic of any particular disease, but results from any morbid condition which produces atrophic paralysis of the intrinsic hand muscles so long as the long extensors of the fingers remain intact. *Progressive muscular atrophy, ulnar paralysis, syringomyelia, cervical pachymeningitis, acute poliomyelitis, amyotrophic lateral sclerosis, and supernumerary ribs* are among the conditions which may give rise to claw-hand to a lesser or greater degree. In any particular case the diagnosis of the underlying condition depends on the results of further investigation.

In *progressive muscular atrophy* (*Fig. 123*), wasting of the intrinsic hand muscles is often an early symptom, and a claw-hand may develop before the long extensor muscles of the fingers have become involved in the disease. All four fingers are usually affected to an approximately equal extent, and there is often marked wasting of the thenar and hypothenar eminences. When the abductor pollicis is also involved the thumb tends to come into line with the fingers and gives an appearance to the hand resembling that of the ape (ape's hand), a condition also seen in *dementia praecox*, though without the muscular atrophy in the latter malady. The flexors of the wrist often become involved before the extensors, with the result that the wrist is hyperextended, and a 'preacher's hand' results. The absence of pain and of all sensory disturbance, the gradual onset, and the general exaggeration of the deep reflexes, serve to distinguish this condition from some of the other causes of claw-hand.

In *ulnar paralysis* the claw-position is more marked in the ring (*Fig. 85, p. 82*) and little fingers than in the middle and first fingers, owing to the fact that the two outer lumbricals are supplied by the median nerve. The adductor pollicis is the only thenar muscle to suffer, but the hypothenar eminence is wasted. If the injury to the nerve is above the point where it gives

off the branch to the flexor carpi ulnaris the latter muscle will also be paralysed, and flexion of the wrist will be carried out with a leaning towards the radial side. In ulnar paralysis the palsy is limited to the muscles supplied by the ulnar nerve, and there is usually some sensory loss in the area of skin innervated by the latter.

Fig. 122.—Claw-foot.

Fig. 123.—Ape's hand due to progressive muscular atrophy; note the wasting of the thenar and hypothenar muscles, and the early stage of claw-hand. (*Fig. 124, C. P. Samonds.*)

The claw-hand of *syringomyelia* (Fig. 124) resembles that of progressive muscular atrophy in general appearance, and may show the modifications to which the terms 'ape's hand' and 'preacher's hand' have been applied. The muscular atrophy is not limited to the distribution of a single nerve, but involves the musculature innervated by the eighth cervical and first dorsal spinal segments—segments in which the gliosis frequently begins. The diagnosis depends on the presence of dissociative anaesthesia, trophic and vasomotor

Fig. 124.—Syringomyelic claw-hand.

disturbances such as whitlows, glossy skin (*peau lisse*), main succulente, and is often corroborated by the occurrence of oculo-pupillary phenomena, nystagmus, scoliosis, and evidence of spastic paralysis in the leg of the same side.

Cervical pachymeningitis only leads to a claw-hand when it interferes with the function of the eighth cervical and first dorsal anterior roots and leaves uninjured the sixth and seventh cervical roots. The condition is generally bilateral with some asymmetry, and it is usually associated with pain and ill-defined disturbances of sensibility in the two arms.

An *acute poliomyelitis* (Fig. 125) affecting the eighth cervical and first dorsal segments, and leaving intact the sixth and seventh cervical segments, is uncommon. The history of acute onset, with constitutional symptoms such as headache, fever, vomiting, and convulsions, affords a clue to the diagnosis. The absence of sensory loss, and the possible presence of atrophic palsies in other parts of the body, form additional data in these cases.

Fig. 125.—Claw hand caused by acute anterior poliomyelitis affecting the posterior horn.

Supernumerary cervical ribs may lead to the production of a claw-hand when they cause neuritic changes in the trunk formed by the eighth cervical and first dorsal contributions to the brachial plexus. The muscular atrophy is preceded by pain in the arm and neck, and sometimes by vasomotor changes and diminution of the radial pulse. Analgesia in the distribution of the eighth cervical and first dorsal root areas may also be detected, but the diagnosis may depend mainly on the skiagraphic discovery of the rudimentary ribs (Figs. 440, 441, p. 544).

E. Farquhar Buzzard.

CLONUS, ANKLE.—(See ANKLE-CLONUS, p. 54.)

CLUBBED FINGERS, or bulbous enlargement of the soft parts of the terminal phalanges, with over-curving of the nails both transversely and longitudinally, are seen characteristically in *morbus caeruleus*, and also in association with fibroid lung. They are distinguished readily from enlargement due to bony changes, such as those of acromegaly and pulmonary osteo-arthropathy.

Minor degrees may occur with almost any disease that leads to persistent congestion of terminal parts, such as mitral stenosis, mitral regurgitation, emphysema, chronic bronchitis, pleurisy with effusion, empyema, chronic phthisis, some forms of aortic or subclavian aneurysm, asthma, pericarditis, adherent pericardium, mediastinitis, or mediastinal neoplasm; in such cases, however, the clubbing has to be looked for it does not thrust itself upon one's notice; it may also pass away again when the cause is removed, for instance when an empyema is cured by operation.

Obvious and extreme finger-clubbing has only two main causes—congenital heart disease with cyanosis (Fig. 126), especially pulmonary stenosis with or without a perforated interventricular septum; and fibroid lung, especially if associated with bronchiectasis.

The distinction between these two will generally be obvious. The former dates from infancy and is associated with extreme cyanosis and a loud pulmonary systolic bruit and thrill; the latter develops later in life, is seldom associated with such extreme cyanosis except when the patient is *in extremis*, and is accompanied by displacement of the heart and other signs of fibrosis of the lung.

Difficulty may arise in those rarer cases of congenital heart disease in which there is no bruit - for instance when the heart gives off a single large vessel, the place of the pulmonary arteries being taken by intercostal vessels - but even here the fact that the lividity is out of proportion to the dyspnoea, and the history that the cyanosis and the finger-clubbing date from soon after birth, afford immediate clues to the diagnosis. Congenital heart disease without cyanosis - patent ductus arteriosus, for instance - does not give rise to clubbed fingers. In lung cases the diagnosis is either obvious from the physical signs, or else, if the abnormal physical signs are so slight as by themselves to suggest little more than bronchitis, the existence of marked clubbing of the fingers is important evidence that the lung trouble is more extensive than this, and that there is really much fibrosis, and probably bronchiectasis, too deep-seated to permit of the usual physical signs being detected at the surface of the chest. An X-ray examination of the thorax will help in detecting such lesions. A moderate degree of clubbing of the fingers is sometimes observed in cases of cirrhosis of the liver (*Fig. 127*), particularly in that type which begins as splenic anaemia - Banti's disease (see p. 49), and also in chronic pancreatitis. This suggests that the changes in the finger-tips have a chemical as well as a mechanical factor in their causation.

Fig. 126. Clubbed fingers in congenital pulmonary stenosis with extreme cyanosis.

Fig. 127. Clubbing of the fingers, developing in the course of cirrhosis of the liver. There was no heart disease and no obvious lung trouble. The patient ultimately died of ascites, and the cirrhosis of the liver was confirmed post mortem.

One cannot always conclude that clubbed fingers indicate visceral disease, however, for instances are known in which many members of the same family, all in good health, have had clubbed fingers as a congenital peculiarity; and if the condition can be familial it is likely that it is sometimes an individual phenomenon quite apart from disease.

Herbert French.

CLUB-FOOT, or TALIPES. Any deformity of the foot not limited to the toes commonly goes under the name of club-foot, or talipes. The diagnosis between the different forms is difficult.

owing to the number of causes and the complicated nature of the deformities. The chief varieties are as follows:

1. Talipes Equinus. In this condition the fore part of the foot cannot be raised to the normal degree. Any healthy adult is able, with the knee straight, to dorsiflex the ankle to such an extent that the ball of the great toe is two or three inches higher than the prominence of the heel. The degree of dorsiflexion is even greater in infants, but with

advancing years the movement becomes limited, especially in women who use high heels, so that old people may hardly be able to dorsiflex the foot beyond the right angle.

2. Talipes Calcaneus. In this condition the heel is depressed and the fore part of the foot elevated. Extension of the ankle is limited, so that the fore part of the foot cannot touch the ground in walking.

3. Talipes Valgus.—The foot is everted and abducted at the ankle-joint, so that the inner malleolus is too prominent and too near the ground.

4. Talipes Varus.—The foot is inverted and adducted at the ankle-joint, so that the outer malleolus is too prominent and too near the ground: in this condition there is in addition serious deformity at the medio-tarsal joint, at which the fore part of the foot is abnormally adducted and inverted.

5. Talipes Cavus. The arch of the foot is too high or hollow. This may be due to depression of the fore part of the foot, of the heel, or of both.

Club-feet may be divided into: (I) *The Congenital*; (II) *The Acquired*.

I. CONGENITAL TALIPES.

Congenital talipes (*Fig. 128*) is usually easy to diagnose because of the history of the presence of the deformity at birth. There are two chief varieties: (1) Equinovarus; (2) Calcaneovalgus.

Sometimes the history is lacking or misleading, and the shape of the feet has been so altered by treatment or neglect that it is very difficult to distinguish the condition from

Fig. 128. Congenital talipes equinovarus—in neglected case.

paralytic talipes, especially that due to paralysis of the lower neuron. In making the distinction it is important to remember that the shortening is usually much less in congenital cases, and that wasting of the muscles, apart from tight splinting, is also much less. Trophic ulcers, and cold and blue feet, which are common in cases of paralysis, do not occur in congenital talipes. Moreover, the toes are not hyperextended at the metatarso-phalangeal joints, a condition commonly present in paralytic talipes. The reaction of degeneration is not present in the congenital type, thus distinguishing it from talipes due to comparatively recent paralysis of the lower neuron. The reflexes are not exaggerated, thus distinguishing it from talipes due to paralysis of the upper neuron. In congenital talipes equinovarus the small conical heel is not only raised but also turned inwards in a characteristic way, and it is generally separated from the inner aspect of the foot by a deep furrow. There is a curious flattening on the outer side of the foot, just in front of the external malleolus, where the skin is dimpled and loose. There is also a furrow on the inner side of the foot opposite the mediotarsal joint. The varus

is always worse than the equinus, whereas in paralytic cases the equinus is usually worse than the varus. With care the overstretched weak muscles can be shown to be capable of voluntary contraction.

II. ACQUIRED TALIPES.

Acquired talipes cases may be subdivided as follows: (1) The paralytic, due to: (a) Disease of the upper neuron; (b) Disease of the lower neuron; (c) Primary muscular disease; (2) Postural, e.g., talipes valgus; (3) Due to fibrosis of muscle with retraction; (4) To bone disease; (5) To joint disease; (6) To contracting scars; (7) To hysteria.

1. The Paralytic.

a. In talipes which is the result of *destruction of the upper neuron* the reflexes are exaggerated and the plantar reflex is extensor; whereas in talipes due to disease of

the lower neuron the reflexes are unchanged, diminished, or lost. Reaction of degeneration may be present with lesions of the lower neuron, absent with lesions of the upper. Coldness and blueness of the feet are only common in lesions of the lower neuron, and the same is true of trophic ulcers, though both may result from changes in the cord when Clarke's column is involved. The shortening and wasting are generally much greater in lesions of the lower neuron, and the distribution of the paralysis is much more irregular than in those of the upper. When the disease of the upper neuron is in the brain it is usual for the arm as well as the leg to be paralysed (*infantile hemiplegia*) (Fig. 129), or both feet may be involved symmetrically (*congenital spastic paraplegia*). Occasionally there may be a cerebral monoplegia. In any case the deformity due to disease of the upper neuron is almost characteristic, and is mostly equinus, usually with a little valgus, but occasionally with slight varus; whereas when the lower neuron is affected the deformity is nearly always equino-varus or talipes valgus. In distinguishing various destructive lesions of the upper neuron the history and the nature of the deformity may help. In *hemiplegia* or *monoplegia* there may be a history of difficult labour, with delivery by forceps, indicating injury to the cerebral cortex, or meningeal hemorrhage with secondary fibrosis of the motor area. The deformity may not be obvious for a year or more after birth, and it is usually noticed first when the child begins to walk. In other cases it may be due to *thrombosis of the cerebral veins* following measles or influenza, or to rupture of some of the cortical veins during whooping-cough or violent fits of passion. *Congenital spastic paraplegia* (Fig. 130) is distinguished by its symmetry, and by the amount of spasm as shown by the unexpected degree of flexion of the ankles that can be produced by firmly pressing upwards the fore parts of the feet. Moreover, there is usually some mental incapacity, and often the history of nervous disease in the family. When the lesion is in the spinal cord there may be a history of spinal injury or evidence of spinal caries, or of growth causing a spastic paraplegia. In *amyotrophic lateral sclerosis* there are paralysis and wasting of the upper limbs of lower neuron type in association with spastic paraplegia of the legs of upper neuron type. *Friedreich's disease*, or *hereditary ataxy*, is an occasional cause of talipes equinus or equinovarus. It can be recognized by the inco-ordination, the nystagmus, the slurring speech, the age of onset, which is usually about six to nine years, the absence of knee-jerk, and the hallux erectus.

Fig. 129. Infantile hemiplegia causing extreme talipes equinus of the left foot.

Fig. 130. Bilateral talipes equinus from congenital spastic paraplegia.

anterior tibial and peroneal group. It is unusual for the paralysis to be limited to the

leg; the thigh is often affected to some extent, and often the opposite leg. It is important to examine for *spina bifida*: talipes due to this is not necessarily symmetrical (Fig. 131); one foot may be involved more than the other, and the deformity is often progressive. I have seen several cases of talipes calcaneovalgus associated with it, and also pure cavus, and one very bad case of equinovarus of one foot and equinovalgus of

Fig. 131. Talipes equinovarus and equinovalgus, due to *spina bifida*.

the other. The foot may drop in *peripheral neuritis* due to diphtheria, lead poisoning, or alcoholism. In each of these conditions there is other evidence of the disease. In many cases of growth in the pelvis the foot may drop owing to invasion of the sacral plexus by the growth, which may be sarcoma of the pelvis, carcinoma of the rectum, or secondary deposits from growth elsewhere. Wounds of the thigh, or the pressure of tight splints in the treatment of fracture, or the forcible extension of a contracted knee, may lead to paralysis of the sciatic nerve, especially of its external popliteal branch. This may lead to talipes equinovarus. A similar deformity may follow injury of the lumbar spine with secondary hamatorachis, or growth anywhere in the course of the sciatic nerve. I have known it follow the use of a Hodgen extension apparatus. *Tooth's neuro-muscular paralysis* (Figs. 81 and 82, p. 79) causes paresis of the anterior tibial and peroneal muscles, with talipes equinovarus and marked cavus, and deformity of the toes. It may be distinguished from infantile paralysis

by the symmetrical affection of both feet, by the wasting of the thenar eminences, and the history of similar deformity in other members of the family, and from the primary muscular dystrophies by the occurrences of reaction of degeneration.

c. Primary Muscular Disease. In primary muscular paralysis (see *Atrophy, Muscular*, p. 78) talipes may develop late in the disease but as a rule the patients do not live long enough for the deformity to become a striking feature. The family history assists the diagnosis, and in the pseudohypertrophic form there is the characteristic way in which the patient raises himself from the supine position by rolling into the prone position and then lifting himself on his toes and hands, and working his hands up the fronts of the thighs.

2. Postural. Talipes valgus may be due to posture or to intrinsic structural weakness of the plantar arches without other disease of any kind (Fig. 132), or it may result from paralysis of the tibial muscles. When a patient makes an attempt to adduct and invert the fore part of the foot the tendons of these muscles can be seen to stand out when they are not paralysed. The foot may be forced into a cramped position by tight boots, and a form of talipes cavus may thus develop, with marked deformity of the toes, which are hyperextended at the metatarso-phalangeal joints and flexed at the others. This condition must not be confounded with a similar one due to paralysis of the small muscles of the foot, especially the interossei and lumbricales, such as may result from infantile paralysis or from peripheral neuritis; deformity may also be due to inflammatory softening of the long plantar ligament, which subsequently stretches and fails to support the plantar arch, as in cases of acute flat foot following gonococcal fibrositis of the foot.

Fig. 132. Talipes valgus and hallux valgus. The patient was not the subject of any other disease; the foot deformity was the only abnormality.

3. Fibrosis and Contracture of the Muscles of the Calf. Very rarely the calf muscles may contract as a result of an ischaemia analogous to that occurring in the forearm, leading to contracture of the wrist and fingers (Volkmann's contracture, *Fig.* 151, p. 178). The same condition may develop as a result of cellulitis of the calf muscles, often associated with compound fracture of the leg, or with acute necrosis of the tibia. In all these conditions it is important to prevent the development of talipes equinus.

4. Bone Disease. Injury or inflammation of the tibia near the epiphyseal lines in youth may lead either to arrest or overgrowth of the affected bone. This is not uncommonly a cause of talipes, which can be recognized if care be taken to make comparative measurements and X-ray examinations of the bones.

5. Joint Disease. In fractures into the ankle-joint, such as Pott's and Dupuytren's fractures, a very bad form of talipes equinovagis may form unless care be taken to correct the deformity and to keep the ankle moving. Talipes equinus may arise as a result of the maltreatment of sprains or arthritis of the ankle, either septic or tuberculous, unless care be taken to keep the joint dorsiflexed during treatment.

6. Contracting Scars. Occasionally talipes equinus follows severe burns or lacerations of the skin of the leg or foot. The diagnosis is usually obvious from the scars. There may be some wasting of the muscles from want of growth of the limb if the burn or injury occurred when the patient had not yet reached full stature.

7. Hysteria. Hysterical club-foot may be suspected from the associated symptoms and confirmed by the absence of any change in the electrical reactions, by the variation of the deformity on different occasions, and the disproportionate amount of spasm, which passes off during sleep and under an anaesthetic.

Finally, if a normal muscle is left in one position over a long period with its points of origin and insertion unduly approximated it may presently be found to be impossible to lengthen it out properly again: it is in this way that contractures of muscles occur during the course of long febrile illnesses—enterica, for instance—when the patient may remain curled up in bed for weeks. If the limbs are extended passively and flexed each day no contracture results, but it happens sometimes that the neglect of this precaution is followed by persistent contracture of what had hitherto been normal muscles, and one of the likely results of this is club-foot.

R. P. Roelands.

COITUS, PAINFUL. (See DYSPARIUNIA, p. 239.)

COLIC is a word often used loosely to include any extreme abdominal pain of a gripping type, doubling the patient up, especially when it is of a kind which tends to wax and wane in intensity. Such pain is due to intense and maintained contractions of the non-striped muscles and may be associated with disease of various abdominal viscera. The causes may be summarized as follows:

1. Biliary. Due to:

Stone in the gall-bladder
Stone in the cystic duct
Stone in the common bile-duct
Stone in a hepatic duct
Acute or subacute cholecystitis
Acute inflammation of the larger bile-ducts
Carcinoma of the gall-bladder
Carcinoma of the cystic duct

Carcinoma of common bile-duct
Carcinoma of ampulla of Vater
Carcinoma of the duodenum
Secondary carcinoma of the portal lymphatic glands
Secondary sarcoma of the portal lymphatic glands
Lymphadenoma of the portal lymphatic glands

Tuberculosis of the portal lymphatic glands
Syphilitic enlargement of the portal lymphatic glands
Chronic pancreatitis
Carcinoma of the head of the pancreas
After injury, with haemorrhage into the portal fissure.

2. Renal. Due to:

Stone in the kidney
Movable kidney (Diehl's crises)
Blood-clot passing from the kidney: After injury; after renal infarction, as in infective endocarditis; from blood diseases, as leukaemia,

scurvy, pernicious anaemia, purpura: from tubercle; from growth
Hydronephrosis
Pyonephrosis
Coli bacilluria
Pyelitis

Pyelonephritis
Tubercle
Carcinoma
Sarcoma
Rhabdomyoma
After pyelography.

3. Ureteric. Due to:

Stone in ureter
Blood-clot
Acute ureteritis

Coli bacilluria
After instrumentation (ureteral catheterization)

From obstruction to the ureter by adjacent tuberculous or calcareous gland.

4. Vesical.—Due to :—

Stone in the bladder
Acute cystitis
Chronic cystitis
Coli bacilluria
Foreign body in bladder
After instrumentation
Blood-clot in bladder
Tubercle of bladder

Villous tumour of bladder
Carcinoma of bladder
Invasion of bladder by carcinoma or sarcoma from without, e.g., from carcinoma of uterus, carcinoma of rectum, or carcinoma of pelvic colon

Irritation of bladder by adjacent inflammation, e.g., appendicitis, parametritis, pelvic abscess, periproctal abscess, pyosalpinx
Bilharziosis.

5. Pancreatic.—Due to :—

Stone in pancreatic duct
Chronic pancreatitis
Acute hæmorrhagic pancreatitis

Carcinoma of ampulla of Vater
Carcinoma of duodenum
Gall-stone impacted in ampulla of Vater

Embolism of pancreas
Injury
Diabetes mellitus, especially when coma is impending.

6. Appendicular.—Due to :—

Adhesions around the appendix
Chronic appendicitis
Thrombosis of appendicular veins

Fæcal concretion within the appendix
Foreign body in the appendix
Inflammation of the lymphatic glands adjacent to appendix

Tuberculosis of the lymphatic glands in the right iliac fossa
Calcareous glands near the appendix.

7. Fallopian.—Due to :—

Salpingitis
Pyosalpinx
Extra-uterine gestation

Tuberculous iliac glands
Calcareous iliac glands
Adhesions

Eroticism
Neurosis.

8. Uterine.—Due to :—

Dysmenorrhœa (q.v.)
Displacement
Adhesions
Endometritis
Injury

Instrumentation
Ergot
Retained products of conception
Carcinoma

Sarcoma
Tubercle
Neurosis
Labour
Chorion-epithelioma.

9. Lead Poisoning.**10. Tabes Dorsalis.**—

Gastric crises
Intestinal crises

Biliary crises
Renal crises

Possibly other crises.

11. Gastric.—Due to :—

Indigestible food
Acute indigestion
Hyperchlorhydria
Adhesions
Post-operative
Injury
Gastric ulcer
Carcinoma
Duodenal ulcer
Alcoholic gastritis

Gall-stones
Cholecystitis
Pyloric stenosis
Visceroptosis
Hæmorrhage into mucosa, e.g., in acute infections : in blood diseases such as leukaemia, pernicious anæmia, purpura, Henoch's purpura

Chronic irritant poisons, notably arsenic, antimony
Lead poisoning
Acute irritant poisons
Tabes dorsalis
Neurosis
Sheer hunger emptiness
Atheroma of the aorta (angina abdominalis).

Intestinal.—Due to :—

Intestinal indigestion
Lead poisoning
Tabes dorsalis
Carcinoma
Subacute diverticulitis
Hirschsprung's disease
Obstructed hernia
Partial volvulus
Intussusception : (a) Acute ;
(b) Chronic
Colitis, whether simple or ulcerative
Dysentery

Cholera
Enteritis
Tuberculous ulceration
Hæmorrhage into the bowel wall from : Injury, Henoch's purpura, blood diseases such as pernicious anæmia, leukaemia, scurvy, purpura
Visceroptosis
Ileocecal kinking
Overloaded cæcum
Chronic overloading of the colon

Impacted feces
The overaction of purgatives, especially aloes, colocynth, calomel, castor oil, gamboge, croton oil, jalap, podophyllin, phenolphthalein, senna, cascara sagrada, scammony, rhubarb
Impacted gall-stone
Mucous colic
Hunger emptiness
Neurosis.

When confronted with a case of extreme abdominal pain in which the cause may be one or other of the many different conditions enumerated above, the point to determine first of all is whether the state of affairs is really one of colic, whatever the kind, or whether, on the other hand, it is one calling for immediate laparotomy. The first thing to do is

to obtain as rapidly as may be a clear account of how the attack came on, where the pain began, where it is at present, whether it is constant or intermittent, and whether there have been similar attacks previously. The history often helps greatly in the diagnosis. The knee-jerks should be tested to exclude tabes dorsalis and its gastric or intestinal crises; the gums may show a blue line if there is lead colic, though if the teeth are clean there may be no blue line, and the exclusion of plumbism (p. 45) may not be easy unless there is a guide to the condition from the patient's employment at some trade in which lead is used. Meanwhile the grave things that will be running through one's mind for immediate diagnosis or exclusion will be:

Acute general peritonitis, due to such causes as:	tuberculous ulcer; ruptured pyosalpinx; uterine infections, possibly after illicit instrumentation; acute diverticulitis	other organ from a blow or other injury
Perforated gastric ulcer; perforated duodenal ulcer; gangrenous appendicitis; ruptured appendicular abscess; perforated intestine from typhoid ulcer (ambulatory type), carcinoma coli,	Ruptured ectopic gestation Twisted ovarian cyst pedicle Twisted subperitoneal fibroid Rupture of spleen, liver, or	Intestinal obstruction from: Strangulated hernia, retroperitoneal hernia, Littre's hernia Acute hemorrhagic pancreatitis Acute irritant poisoning.

For all these except the last urgent laparotomy is needed, and the main decision will at first be upon the point of whether to operate or not, irrespective of refinement in diagnosis. Mistakes are apt to arise more in the young, and in the old and debilitated, than in those of middle life; children in particular are very deceptive in the signs of peritonitis they may present, especially when a lull comes after the first seriousness of the onset; one needs to be most cautious in diagnosing colic as against peritonitis in anybody under adult age, purulent fluid being present in the abdomen sometimes when the abdominal wall seems perfectly supple and when a stage has been reached when the small patient seems to be suffering but little pain on palpation of the abdomen.

In many cases, on the other hand, the colic nature of the diagnosis may be obvious at once; some of the points to pay particular attention to are:

The Condition of the Abdomen and its Wall. The surface of the abdomen should be uncovered in its entirety, and it should be examined in a good light. If there is good movement of the whole of it on respiration one may feel happier than if it remains motionless as the patient breathes. *Absence of movement* does not tell one that there is more than colic; presence of movement does not exclude peritonitis, and still less intestinal obstruction; but, other things being equal, the less the abdomen moves the more should one be on the alert to undertake urgent surgical measures. Distinct from mobility is the *rigidity* of the wall: it may not be rigid even when there is peritonitis, especially in children and in debilitated adults, but if the whole abdominal wall is rigid as well as motionless the probability of peritonitis is great. There is often no rigidity in cases of intestinal obstruction or even of acute hemorrhagic pancreatitis, so that absence of rigidity does not mean that there is no call for laparotomy; but a combination of rigidity and of non-mobility renders it impossible to be satisfied with a diagnosis of some sort of colic only.

There may be both rigidity and non-mobility even when colic only is the cause of the pain, however, so that other features of the case call for attention in conjunction with them. It might be thought that one would be helped by the general state of the abdomen

whether it looks normal, or is retracted, or is blown out. The varying degrees of distention that may accompany both colic and the graver affections are so great that one cannot place much reliance on it in coming to a decision. There is often retraction of the abdomen in the earlier stages of peritonitis, followed by progressive distention; with intestinal obstruction or hemorrhagic pancreatitis there soon will be distention, but it may not be apparent when the patient is first seen; with colic conditions, especially intestinal colic, there may be enormous distention almost at the very first, and yet on the other hand there may be no distention at all.

If there is dullness in the flanks, shifting when the patient is rolled up to one side, this indication that free fluid is present shows that colic is only part of the diagnosis; and if by chance a friction rub is to be detected over the liver or the spleen one has direct evidence of the existence of peritonitis. Such peritonitic rub is heard only exceptionally, however, even when acute peritonitis is undoubtedly present.

Examination of the Hernial Orifices. This is very important, lest there be a hernia that has become obstructed or strangulated; femoral, inguinal, or umbilical hernia will generally be obvious, though sometimes the amount of bowel or omentum strangulated may be so small that it can be recognized only when the greatest care is taken in palpation. Obturator and retroperitoneal hernia may be impossible of recognition until operation is performed.

The Pulse-rate. This will often afford crucial evidence in deciding whether to operate or not. It is not so much the actual pulse-rate at the time that counts, as the progressive change in the pulse-rate when it is counted at ten-minute intervals. In cases of pure colic the pulse is generally not unduly fast, but it may be very rapid if the patient is excited or flustered; in cases of peritonitis or obstruction the pulse may not be very rapid when the patient is first seen; but when the case is watched for a little while the pulse-rate in a case of colic will tend to diminish in rapidity at successive ten-minute counts, whereas it will generally rise progressively when there is a more grave condition calling for surgery. It is most important to record the pulse-rates at short intervals when the diagnosis is in doubt; a progressively rising rate is an indication of grave danger for which speedy surgical help will generally be wanted. The following figures are typical examples:—

PROGRESSIVE PULSE-RATES.

Time :	3.10	3.20	3.30	3.40	3.50	4.0	4.10	
Acute intestinal colic	110	108	96	90	90	96	88	<i>Steady recovery</i>
Acute appendicitis, with early general peritonitis	88	94	96	100	98	102	110	<i>Operation</i>

The Temperature. This helps less than might be supposed; with many forms of colic there is no rise of temperature at all; but there may be no pyrexia, or even a sub-normal temperature, in the earlier stages of intestinal obstruction, or with peritonitis if the patient is collapsed; on the other hand, especially with biliary or renal colic where there is infection as well as a stone in the gall-bladder or kidney respectively, there may be pyrexia and even a rigor, though the condition is colic and not peritonitis. The pulse-rate is a better guide than is the temperature chart in making the differential diagnosis.

Vomiting. This is another symptom which is common both to colic and to graver intra-abdominal lesions, so that relatively little reliance can be placed upon it as a means of differentiation. Biliary colic may be associated with severe and recurrent vomiting fully as severe as that caused by general peritonitis; other things being equal, however, the more persistent the vomiting the more prone should one be to entertain the idea of performing laparotomy.

The Facies of the Patient. The patient's facies is sometimes of the greatest importance in helping one to diagnose between colic and peritonitis; the Hippocratic anxious drawn facies of peritonitis may be almost pathognomonic, though the absence of such facial expression does not serve to exclude acute peritonitis, especially in the dangerous semi-quiet phase of the latter so apt to follow the initial severity, especially in children; deluding one into thinking that there is real improvement when in fact the time for saving life by laparotomy is slipping by. The facies is much more anguished, as a rule, with peritonitis than it is with colic, but the absence of an anguished face should not count for much if there is a rising pulse-rate and a rigid abdomen. Experience is the main factor in helping one to a decision in many cases in which one is guided more by the look of the patient where there is clearly some serious abdominal trouble.

The quiescence or general physical activity of the patient may sometimes help one much in diagnosis. With peritonitis he generally lies quite still, generally on his back, and often with the knees drawn up; with colic, especially in the exacerbations, he often throws himself about moaning and groaning, possibly turning over to press his abdomen across a pillow, doubling himself up in active pain, or squeezing a hot bottle firmly against his abdominal wall; the quieter the patient lies the less likely is the condition to be colic only; the more he throws himself about or presses things against his abdomen the less likely is the lesion to be peritonitis.

The *bowels* may act naturally, frequently, or not at all, and their behaviour helps but little in the differential diagnosis except in connection with acute intestinal obstruction: in the latter there may be an initial evacuation from the bowel lying below the site of obstruction, but thereafter there will be no result from enemata or purgatives—a fact which will at once arouse suspicion that there is obstruction calling for laparotomy; the need for the latter will become increasingly obvious if vomiting persists and if the abdomen becomes distended and peristalsis visible: and yet there are curious cases of acute colic associated with what appear to be all the typical signs of acute intestinal obstruction, even to the extent of extreme meteoric distention of the abdomen and faecal vomiting, in which no organic cause is found when the abdomen is opened, the patient recovering without any exact diagnosis being arrived at.

The *urine* may afford help in diagnosis: the existence of hæmaturia, albuminuria, pyuria, or bile in the urine may help to decide in favour of renal or biliary colic as against peritonitis or intestinal obstruction. Hæmaturia is probably the most important; albumin, pus, or bile may be present in association with graver lesions than colic. Frequency of micturition is suggestive of a renal or vesical lesion, but should not be attributed to such too lightly, for analogous frequency may result from peritonitis, especially from peritonitis that has started from some inflammatory lesion near the pelvis—appendicitis, for example, or pyosalpinx or parametritis.

Jaundice may result from peritonitis: but occurring in a case in which colic is a likelihood it generally points to biliary colic from cholecystitis or from gall-stones. It is not, however, an early symptom with these: more often the difficulty of diagnosis is to-day, and the occurrence of jaundice to-morrow or next day, when the gall-stone is passing down the common bile-duct and gives rise to jaundice which serves to clinch a diagnosis which may have been in grave doubt when the pain in the abdomen began or was at its height.

Rectal and vaginal examination should be resorted to whenever practicable: digital examination of the rectum in particular may sometimes afford valuable evidence in assisting the diagnosis. A tender bulging appendicular swelling may be felt: or a ballooned bowel if there is obstruction: or a sense of free fluid in the pelvic pouch of the peritoneum may serve to indicate that there is something more the matter than some variety of colic.

The *knee-jerks* and the *pupil reflexes* should be tested in all such cases, lest *tabes dorsalis* be the cause of gastric or other abdominal crises simulating peritonitis or intestinal obstruction: the gums should be examined for a *blue line*, and the occupation of the patient inquired into lest *plumbism* be the cause of the severe abdominal colic. The absence of a blue line does not exclude plumbism, however: nor is it impossible for either a tabetic or a plumbic case to have a perforated gastric ulcer or acute appendicitis, and it is clear that, notwithstanding all the many points there should be to guide one, clinical experience is all-important in making the diagnosis in many of these cases.

Referred Pains in the Abdomen constitute another group of difficulties in diagnosis that need to be borne in mind in certain cases. Broadly speaking, such referred pains come from two sources, namely: (1) *Intrathoracic*; (2) *Spinal*. Very acute abdominal pains may result from either source, but it may suffice to enumerate these without entering into full discussion of each:

1. *Intrathoracic Causes of Referred Abdominal Pains that may be mistaken for Colic:—*

Acute lobar pneumonia	Aortic aneurysm	Myocardial degeneration, especially fibroid heart
Acute pleurisy	Epithelioma of the œsophagus	Dissecting aortic aneurysm
Infarct of the lower lobe of one lung	Atheroma of the lower thoracic aorta causing 'angina abdominalis'	Atheroma of the coronary arteries.
Acute dilatation of the heart		

2. *Spinal Causes of Referred Abdominal Pains that may be mistaken for Colic:—*

Tuberculosis of the spine (Pott's disease)	Myeloma of the vertebrae	Pachymeningitis of the spinal cord (generally syphilitic)
Carcinoma, secondary, in the vertebrae	Spondylitis deformans	Spinal meningitis
Sarcoma, primary, in the vertebrae	Infective arthritis of the spine	Hæmatoma after injury
Sarcoma, secondary, in the vertebrae	Osteo-arthritis of the spine	Fracture of the spine
	Actinomycosis of the spine	Aortic aneurysm eroding the spine.
	Gumma of the spine	

Certain Vascular Lesions within the abdomen may give rise to the greatest difficulty sometimes in diagnosis, as between themselves on the one hand, or either acute colic or acute peritonitis on the other; fortunately they are relatively rare, but they include :-

Thrombosis of mesenteric vein branches	Acute 'angina abdominalis' from atheroma
Thrombosis of inferior vena cava	of the abdominal aorta.
Dissecting aneurysm of the aorta	

Thrombosis of mesenteric vein branches is probably not very uncommon, for phleboliths are found frequently in the course of routine post-mortem examinations; the diagnosis of the actual thrombosis is seldom possible at the time, however, unless there is either a pulmonary embolism, or an acute abdominal attack followed by the passage of blood and mucus per anum, as a complication. Many intra-abdominal thromboses remain entirely unsuspected, but they are the commonest cause of the catastrophic sudden deaths that may occur about the tenth day after abdominal operations that have been apparently successful.

Thrombosis of the inferior vena cava is much rarer but much more serious. The patient is seized with violent abdominal pains, vomiting, and collapse; he may seem to have developed acute peritonitis from, for example, a perforated gastric ulcer; but with so much collapse that it may be deemed inadvisable to operate, the diagnosis being in doubt until autopsy is performed. In less severe cases the abdomen may be opened and, to the surprise of all, nothing to account for the symptoms may be found; if the patient survives, the nature of the trouble may never be known unless, if the inferior vena cava is much stenosed by the clot or entirely blocked by it, extreme œdema of both legs, thighs, lower abdomen, and back to halfway up the loins, ensues and draws attention to the vascular nature of the lesion. In milder cases in which the clot forms a coating only to part of the inside of the vein, symptoms may not be severe enough to call for laparotomy, and the case may be regarded vaguely as some form of colic, recovery resulting after a variable degree of recurrent abdominal pain for which the actual cause may remain permanently obscure.

Dissecting aneurysm of the abdominal aorta is extremely rare, but when met with it is found to simulate an extremely urgent surgical abdominal case; generally associated, however, with so much collapse that no operation is done and the diagnosis is made at autopsy.

Angina abdominalis is similar in the urgency and severity of its symptoms to its analogous angina pectoris, except that the acute pain and distress are referred to the central and upper parts of the abdomen instead of to the precordial region, left shoulder and arm. It results from senile, alcoholic, or syphilitic atheroma of the abdominal aorta. The first attack will almost certainly be diagnosed either as acute colic—gastric, intestinal, or biliary—or as a perforated gastric ulcer, or as some analogous intra-abdominal lesion. Laparotomy may be performed and nothing be found. The attack passes off, generally only after

have been colic-like exacerbations for days whilst the patient is confined to bed; after an interval there will be a precisely similar bout, and then others; and it will be found that the attacks do not fit in properly with any of the better recognized forms of colic. Vomiting is common, yet the pains do not point clearly to stomach, or to intestine, or to gall-bladder, or to kidney. The age of the patient, his blood-pressure, and the condition of his heart and arteries may then suggest an arterial cause, and the diagnosis of angina abdominalis may be arrived at more by surmise than from any direct or positive proof.

Having come to the conclusion that other things can be excluded, and that in a given case of severe abdominal pain the cause is colic of some kind, the next step is to diagnose whether the pain is biliary, renal, ureteric, vesical, pancreatic, appendicular, Fallopian, uterine, gastric, or intestinal. It would require a volume to go into all the points that help one to decide between these and between the different possible causes in each case. The most important points at the outset are the patient's story and the site of maximum pain. With these to guide one, it will often be the reverse of difficult to locate the site of the colic; and then the differential diagnosis of the various causes resolves itself into a search for evidence for and against each of the conditions enumerated in the list given

above. Colic which is now here, now there, is generally intestinal; other types are more often constant in position. Without jaundice it may be difficult to decide in favour of gall-stones and against duodenal ulcer, unless there is X-ray evidence of the latter; with jaundice, colic is more often biliary than not, though both pains and jaundice may result from duodenal ulcer or from chronic pancreatitis, and each of these may be mistaken for gall-stones until laparotomy is performed. Pancreatic colic is always difficult to diagnose unless sugar is present in the urine to guide one, although other pancreatic tests (p. 128) may assist the diagnosis. Of all forms of colic, perhaps the one most liable to be misdiagnosed is ureteric colic on the right side, the result commonly of either coli bacilluria or of a small ureteric calculus, generally mistaken for appendicitis. Coli bacilluria is far commoner than calculus, and chronic appendicular colic should not be diagnosed until coli bacilluria has been excluded by urine culture.

Herbert French.

COLOUR BLINDNESS.—(See VISION, DEFECTS OF, p. 920.)

COMA is a state of unnatural, heavy, deep and prolonged sleep, often accompanied by slow stertorous or irregular breathing, and frequently ending in death. It may be due to a large number of different causes, which may be classified into two main groups, namely: (*A*) Cases in which coma is not a prominent symptom early in the malady, but only in a late stage, when the nature of the disease has already been suggested by other symptoms; and (*B*) Cases in which coma comes on early and may be the most prominent feature of the case.

Group A includes—

1. Certain Severe Fevers in which coma may occur as a terminal phenomenon:—

Typhus fever	Rheumatic fever	Influenza maligna
Typhoid fever	Yellow fever	Spirochaetosis icterohaemorrhagica (Weil's disease)
Cholera	Blackwater fever	Lobar pneumonia
Dysentery	Malignant malaria	Small-pox.
Measles	Infective endocarditis	
Scarlet fever	Diphtheria	

2. Acute Inflammatory Lesions of the Brain or the Cerebral Meninges:—

Acute encephalitis	Epidemic cerebrospinal meningitis, or spotted fever	Sleeping-sickness (the cerebral stage of trypanosomiasis).
Suppurative meningitis	Encephalitis lethargica	
Tuberculous meningitis	(‘sleepy sickness’)	
Posterior basal meningitis		

3. Certain Less Acute Lesions of the Central Nervous System:—

Cerebral tumour	Post-epileptic state	Disseminated sclerosis
Cerebral abscess	General paralysis of the insane	Syphilis of the brain.

4. Diseases in which General Metabolism is probably at Fault:—

Uremia	Cholæmia	Raynaud's disease
Diabetes mellitus	Addison's disease	Myxœdema.

5. Late Stages of certain other Maladies that exhibit prominent symptoms other than Coma before Coma supervenes:

Acute yellow atrophy of the liver	Pernicious anaemia	Aeroplane-dope poisoning
T.N.T. poisoning	Leukæmia	Botulism.
Phosphorus poisoning	Cirrhosis of the liver	
	Kala-azar	

Group B includes—

1. The Results of Head Injury:—

Compression by meningeal hæmorrhage	Concussion	Fracture of the base of the skull.
	Depressed fracture	

2. Vascular Lesions of the Brain:—

Embolism	Thrombosis: (<i>a</i>) Arterial; (<i>b</i>) Of a venous sinus, such as	the superior longitudinal or the cavernous.
Hæmorrhage		

3. The Acute Effects of Drugs, particularly : —

Alcohol	Sulphonal	Sewer gas
Opium	Chlorodyne	Carbon dioxide (e.g., in disused wells, after-damp in mines)
Morphia	Chloralamide	Trional
Omnopon	Phenazone	Tetronal
Heroin	Phenacetin	Bromides
Carbolic acid	Pyramidon	Chloroform and other anaesthetics
Oxalic acid	Petrol fumes, or the products of incomplete combustion of petrol in garages or motor boats	Myrtol
Carbon monoxide	Fire damp, in mines (marsh gas)	Eucalyptus oil
Coal gas		Camphor
Absinthe		Luminal.
Chloral hydrate		
Veronal		

4. The Chronic Effects of Chemicals, especially plumbism (saturnine encephalopathy).

5. The Effects of Extremes of Temperature : Heat stroke Excessive cold.

6. Excessive Loss of Blood from :

Ruptured tubal gestation	Hæmatemesis	Intestinal bleeding
Postpartum hæmorrhage	Duodenal bleeding	Ruptured aneurysm.
Hæmoptysis		

7. Stokes-Adams' Disease.

8. Sudden Nervous Shock.

9. Hysterical Trance.

Although it is generally possible to make a broad distinction between the two groups enumerated above, it is necessary perhaps to point out that some conditions which usually give rise to other symptoms before they produce coma sometimes pass unrecognized until coma supervenes. This applies, for example, to certain cases of diabetes mellitus, uræmia, suppurative meningitis, or cerebral abscess or tumour ; whilst, conversely, some conditions which usually exhibit coma early may not do so until after there have been other symptoms to indicate the nature of the case. It is not necessary to enter into the differential diagnosis of those conditions in which other prominent symptoms have preceded coma.

When coma is either the first or the most prominent symptom in the case, it is important to arrive as near the correct diagnosis as possible at the earliest moment, the case being relegated to one or other of the following four classes, which differ from one another radically as regards treatment :—

1. Cases in which immediate trephining is required, e.g., for meningeal hæmorrhage.
2. Cases in which active treatment by lavage of the stomach or by the administration of antidotes is required, as in opium or other poisoning.
3. Cases in which active medicinal or physical treatment is required : for instance, the coma requiring the administration of alkalis and insulin, or uræmia requiring section, or coal-gas poisoning requiring the administration of concentrated oxygen.
4. Cases in which absolute rest is indicated, especially in cerebral hæmorrhage, or in fracture of the base of the skull.

When investigating a case, notice first whether there is any evidence of *unilateral paralysis* : the pupils may be markedly unequal, one cheek may be more puffed out on expiration than the other, one arm or leg may fall more limply than the other ; there may be differences between the two knee-jerks or the two plantar reflexes ; there may be conjugate deviation of the eyes. If there is distinct evidence of unilateral paresis or paralysis, there is almost certainly a cranial or intracranial lesion — hæmorrhage, embolism, fracture, tumour, abscess, thrombosis, or meningitis. Next, examine the head with particular care to see if there are any signs of injury : the presence of a scalp wound or even of a fracture does not of course prove that this is the primary cause of the coma, for the patient may have become unconscious, from a cerebral hæmorrhage for example, and in falling may have struck his head, in which case the injury is due to the coma, and not the coma to the injury. Some of the greatest difficulties in diagnosis arise on this account, particularly when the patient has previously taken sufficient alcohol for his breath to smell of it, and to suggest that he is drunk. Careful observation for several hours may be

required before the diagnosis can be settled, and even then errors are sometimes unavoidable. A clear history is generally lacking, but if available it often assists materially in deciding the nature of the case. The ears and nose should be examined with care to see whether cerebrospinal fluid or blood is coming from either, as an indication that there is a fracture at the base of the skull; blood coming forward into the subconjunctival tissue may afford similar evidence.

Cerebral hemorrhage is much more common in an elderly than in a young person, whilst the reverse is true of embolism. The latter may occur instantaneously, whilst hemorrhage produces coma rather more gradually; and thrombosis, syphilitic or otherwise, often leads to hemiplegia so gradually that no coma occurs. The presence of albuminuria with casts, with a high blood-pressure as measured instrumentally; the history, in an elderly man, of a previous seizure of a similar kind with definite hemiplegia—especially if there is also an enlarged heart with a lumpy first sound at the impulse, or perhaps a local systolic bruit there, with a ringing aortic second sound—would all indicate cerebral hemorrhage, associated with defective arteries and perhaps with granular kidney. Albuminuric retinitis should be looked for. Strong evidence in favour of *cerebral embolism* would be afforded by a previous history of acute rheumatism and the existence of a presystolic or other bruit indicative of organic heart disease, especially if there are signs (p. 45) suggesting that fungating endocarditis has supervened.

Supposing there is no evidence of a unilateral paralysis it does not immediately follow that none of the above conditions are present: one form of cerebral hemorrhage in particular that may cause no unilateral paralysis is *pontine hemorrhage*; this might be suggested at once by the very small, almost pin-point pupils, though similar pin-point pupils may be due to *opium poisoning*. The thermometer affords a means of diagnosis between these, for opium poisoning leads to a subnormal temperature, whilst hemorrhage into the pons Varolii causes the temperature to rise even to the point of hyperpyrexia (*Figs. 133, 134*). The diagnosis of other varieties of coma due to poisoning can seldom be arrived at accurately unless the circumstances of the case either allow of an analysis of the gastric contents, or else point to the patient having taken an overdose of one of the drugs mentioned in the above list, either accidentally or with suicidal intent. The bottle may be found near the patient.

Coma due to poisoning by *carbon monoxide* is sometimes obvious from the patient's bright cherry-red colour: it is impossible to convert the carboxyhaemoglobin in his blood into reduced haemoglobin by the ordinary ammonium sulphide method; and there is generally direct

Fig. 134. Temperature chart in a case of morphia poisoning ending in recovery.

evidence of the mode of poisoning, such as the fact that the patient is found in a room with the windows shut and the gas turned on, or has been subjected to the fumes of slow combustion from a stove, brazier, limekiln, or some other fire which has been burning with an insufficient supply of oxygen.

Saturnine encephalopathy is very variable in its symptoms: it may take the form of epileptiform convulsions, more or less dementia, continued coma, acute mania, or severe and long-continued headaches with some degree of general strangeness of demeanour or behaviour; indeed, its multifariousness is one of its chief features. The occupation of the patient may point to the diagnosis forthwith.

Myxedema is generally diagnosed from the facies (p. 50) and general state of the subcutaneous tissues, or from the results of thyroid treatment; occasionally, however,

Fig. 133. Temperature chart showing typical pyrexia due to pontine hemorrhage of rapidly fatal type.

one meets with a case in which the mental symptoms so far outweigh the others that the nature of the malady is apt to escape attention altogether. An attack of coma is rarely the first sign, though it may be; more often there is a longish history of progressive mental slowness, sometimes with delusions, and often associated with attacks of irascible excitation alternating with fits of depression, or with bouts of mental lethargy stopping short, as a rule, of actual coma.

Coma due either to *heat stroke* or to exposure to *excessive cold* is generally indicated by the collateral evidence, especially as regards the temperature of the patient's surroundings, or his having been exposed to very strong sun's rays when at work. The chief difficulty will be to make certain that there is not any vascular lesion of the brain. When there is doubt, the course of the case may indicate its nature, heat stroke either recovering rapidly or ending fatally with hyperpyrexia; but sometimes, even in a fatal case, the diagnosis may remain in doubt until a post-mortem examination has been made.

Acute encephalitis is a disease of children rather than of adults; its general symptoms are those of acute meningitis: the patient becomes unconscious more rapidly, however, than is usual with the latter, and yet, notwithstanding the apparent severity of the illness, recovery may occur, either within a few days or a week or two. The diagnosis rests upon the course and recovery, for in the earlier stages it will nearly always have been regarded

FIG. 155. Optic neuritis in the right eye, and segmental optic atrophy in the left eye, in the same patient, a case of chronic plumbism. The white segment of atrophy in the left optic disc results from degeneration of those fibres which come from the macular region, the remaining optic fibres not being atrophic.

as acute meningitis. The same applies to acute *thrombosis of the superior longitudinal sinus*, the diagnosis between which and acute encephalitis or meningitis is generally one of opinion only, unless operative measures are resorted to, or a post-mortem examination made.

Optic neuritis, as well as headache, vomiting, and general convulsions, may occur in all three.

Thrombosis of the cavernous sinuses may simulate encephalitis or meningitis in the early stages, but generally leads to increasing exophthalmos or proptosis with variable strabismus, these last two symptoms, particularly the progressive proptosis, making the diagnosis clear in what might otherwise be a very obscure case.

As regards *encephalitis lethargica* ('sleepy' sickness), the diagnosis may be very easy or very difficult according to the clinical symptoms of the case. The common type is that in which the patient becomes increasingly drowsy in association with more or less febrile disturbance: apathy is followed by somnolence, general lethargy, stupor, coma without abnormal physical signs in the systemic viscera; there is often paresis of ocular or facial muscles; the cerebrospinal fluid may show no abnormality on lumbar puncture; optic neuritis, though found occasionally, is generally absent; death may ensue, and the diagnosis be confirmed by skilled histological examination of the mesencephalon. On the other hand, after days or weeks of stupor or coma the patient may recover slowly, and either completely, or with ocular or facial paresis, or with long-continued diminution of mental acumen. It may require very special clinical knowledge to make the diagnosis in other cases, however; and sometimes, if the patient recovers, the nature of the case

will remain permanently one of opinion only; this applies particularly, perhaps, to abortive cases in which drowsiness without any cranial nerve paresis is the only symptom, cerebrospinal fluid and optic discs remaining normal, and the patient recovering in two or three weeks; or to other cases in which, besides the stupor or coma, rhythmic tremors of the head and neck or arms may temporarily simulate paralysis agitans; or when cerebellar ataxia or nystagmus may at first suggest disseminated sclerosis; or when definite hemiplegic symptoms develop and suggest an intracranial hemorrhage or tumour. The protean character of the symptoms depends on the variable degree and severity and distribution of the exudative lesions in the mesencephalon, cerebellum, pons, and medulla, and in not a few cases the diagnosis can only be established by histological post-mortem examination: to the naked eye the brain tissues may not appear abnormal even at autopsy. Convulsions may occur, but they are generally absent. Somnolence, stupor, and coma are the most constant symptoms; vomiting is rarely a marked feature, unless perhaps in the earlier stages of the disease; and in many instances the diagnosis is guessed at because of the sleepiness or stupor of the patient, who clearly has some intracranial lesion, but one which does not cause changes in the optic discs and cerebrospinal fluid that would be likely to accompany alternative lesions such as cerebral tumour or acute or tuberculous meningitis.

General paralysis of the insane does not as a rule give rise to coma and epileptiform convulsions until the nature of the case has been indicated already by the mental and physical changes—particularly the ideas of grandeur, the loss of highest cerebral control in one way or another, the changes in disposition, and the inability to perform the finer movements required for writing, dancing, playing the piano or violin, painting, and so forth, in which the patient may at some time previously have been an adept. Occasionally, however, notwithstanding some alterations in the mental character, the diagnosis of general paralysis may not have entered one's mind in a given case until a sudden syncopal seizure, with or without convulsions, attracts particular notice to it. It is not impossible that such a case may even then be mistaken for one of severe cerebral hemorrhage, and it may be treated as such until it is found that the coma, severe though it may have been, passes off rapidly in a way that would not have been the case had it been a hemorrhage of corresponding severity. The recurrence of these attacks will make the diagnosis certain, even if it remains in doubt for a time, and examination of the cerebrospinal fluid for excess of lymphocytes or for Wassermann's serum reaction will serve to clinch the diagnosis in most cases.

Coma due to *malaria* is apt to be mistaken for other things unless circumstances suggest the need for the examination of blood-films, in which the malarial parasites will be found; cerebral malaria may simulate insanity of maniacal, melancholia, or dementia types before actual coma sets in; or coma may develop without previous mental symptoms if the numbers of malarial parasites are, as they may be, so great as virtually to plug the cerebral capillaries.

Severe *hemorrhage* other than cerebral as a cause for coma is usually indicated at once by the sudden extreme blanching, not only of the patient's cheeks, but also of his lips and mucous membranes. The pulse-rate rises to 100, 120, or even 150, according to the amount of blood that has been lost; if there has been external evidence of the hemorrhage, the differential diagnosis will be arrived at as discussed under such headings as HEMATEMESIS, HEMOPTYSIS, METRORRHAGIA, etc. If the bleeding has been internal in a healthy person the commonest cause is duodenal ulcer in a man, pelvic hematocele or ruptured tubal gestation in a woman; similar blanching in cases of typhoid fever would point to intestinal bleeding. The coma in such cases comes on suddenly, but it does not long remain profound. It is often preceded by amaurosis, and may be accompanied by epileptiform convulsions, so that acute uræmia may be simulated.

When an aortic aneurysm ruptures into a bronchus, the œsophagus, trachea, stomach, or bowel, the amount of blood-loss seldom leads to coma, but rather to sudden death; sometimes, however, when the bleeding is into some closed space such as the mediastinum or retroperitoneal tissue, the blood-escape is checked to some extent, and acute blanching with coma precedes further bleeding and death. Rupture of an aortic aneurysm into the pericardium causes sudden death before the amount of blood lost has been sufficient to produce marked blanching.

The phenomena of Stokes-Adams' disease are described on p. 108.

Hysterical or functional *trance* is an affection of young women, and it is not very common: the diagnosis is arrived at by a process of exclusion, and until the case has been watched for some time its nature may not be obvious unless there have been other hysterical symptoms previously (p. 570). It is a dangerous diagnosis to make until every other possible cause for coma has been considered and satisfactorily excluded, for it is not difficult to jump to the conclusion that coma in a girl or young woman, really arising perhaps from a cerebral tumour or abscess, is due to a neurosis. It is most important to examine the optic discs with great care, lest there should be optic neuritis, the latter never being functional.

Herbert French.

CONJUNCTIVITIS.—(See EYE, ACUTE INFLAMMATION OF, p. 285.)

CONSTIPATION.

1. CHRONIC CONSTIPATION.

Most of the indigestible residue of a meal normally reaches the pelvic colon in less than sixteen hours, and in defaecation all the contents of the pelvic colon are evacuated. Some of the residue of a meal taken eight hours after defaecation should be excreted at the next defaecation in individuals whose bowels are opened every twenty-four hours. If, however, the bowels are only opened on alternate mornings—a condition which is not necessarily pathological—forty hours instead of sixteen would elapse before some of the residue of the meal would be excreted. Constipation may therefore be defined as *a condition in which none of the residue of a meal, taken eight hours after defaecation, is excreted within forty hours*. Constipation thus defined can be recognized by giving three charcoal lozenges with food eight hours after defaecation: if a blackened stool is not passed within the next forty hours the patient is constipated.

The abnormal action of the bowels in constipation may manifest itself in three different ways:

1. *Defaecation may occur with insufficient frequency.* A daily action of the bowels is merely a matter of convenience, and many people in perfect health only defaecate once in two or three days. As a rule, however, an individual may be regarded as constipated if his bowels are not opened at least once in forty-eight hours.

2. *The stools may be insufficient in quantity and a certain amount of faeces is retained,* although the bowels may be opened once daily or more often. This condition (cumulative constipation) can be differentiated readily by the charcoal test from that in which the bowels are properly emptied but the faeces are very small in quantity owing to the diet or to the unusually active absorptive power of the intestines.

3. *The bowels may be opened daily, yet the faeces are hard and dry, owing to prolonged retention before excretion:* the deficient quantity of water in the stools also renders them less bulky than normal. The stools may be similar in character when an excessive quantity of fluid is lost by other channels, as in diabetes. By means of the charcoal test it is easy to determine whether constipation is also present.

After constipation has been diagnosed, it is necessary to determine its cause. The first essential is to distinguish between two great classes of constipation: that in which the passage through the intestines is delayed whilst defaecation is normal *Intestinal Constipation*: and that in which there is no delay in the arrival of faeces in the pelvic colon, but their final excretion is not performed adequately *Pelvi-rectal Constipation or Dyschezia*.

A.—DIAGNOSIS BETWEEN INTESTINAL CONSTIPATION AND DYSCHESZIA.

A rectal examination should be made in the morning, after an attempt has been made to open the bowels without the assistance of medicine, enemata, or suppositories. If more than a very small quantity of faeces is found in the rectum, dyschezia may be diagnosed. If the rectum is almost or quite empty, the constipation must be due to delay in the passage through the intestines, except in the uncommon cases of dyschezia in which there is inability to pass faeces from the pelvic colon into the rectum. The latter condition

can be recognized on rectal examination, if the pelvic colon is felt through the front wall of the rectum to be filled with solid faeces: the presence of faeces in the pelvic colon can also be proved by sigmoidoscopic examination made at once, without preparation of the patient by washing out his bowels.

At the same time the abdomen should be palpated. If scybala are felt in any part of the colon, intestinal constipation must be present. This is, however, not necessarily the case if faeces are felt in the iliac or pelvic colon, as the rectum in dyschezia may be so full of faeces that retention occurs secondarily in the pelvic and iliac colon: such a condition would be recognized by the rectal examination.

When a patient feels that there is something in his rectum which he cannot expel at all, or that after defecation the relief is incomplete, dyschezia is probably present. The absence of this symptom does not exclude the possibility of dyschezia, as the rectum is often so insensitive in such cases that no sensation is experienced, even when it is greatly distended with faeces. The frequent passage of very small pieces of hard faeces (fragmentary constipation), or the occurrence of pseudo-diarrhoea in which small fluid stools, sometimes containing hard fragments of faeces, are passed, although the charcoal test shows the presence of constipation, are both symptoms suggestive of dyschezia.

Some indication, which is not, however, absolutely reliable, can be obtained from the results of previous treatment. Patients who have found that diet and mild aperients readily give them relief are in all probability suffering from intestinal constipation. Those who have obtained better results with enemata, and particularly with suppositories, probably have dyschezia. Dyschezia is of course also present in those patients who have to dig out the faeces from the rectum with their fingers.

Fig. 136. Dyschezia in a boy of 19, associated with chronic inflammation of a tender barium appendix. Thirty-six hours after an opaque barium breakfast most of the barium has collected in the dilated pelvic colon and rectum, a little being still present in the caecum, vermiform appendix, and ascending colon: in spite of the accumulation in the pelvic colon the patient felt no desire to defecate. (Fig. 137, P. J. Briggs.)

through some part or all of the colon, and occasionally the small intestine: in dyschezia there is no delay in the intestines, but the act of defecation does not empty the pelvic colon and rectum completely (Figs. 136, 137).

Fig. 137. Sigmoidoscopy after a barium breakfast in a boy with constipation. A.C., ascending colon; T.C., transverse colon. T.C., thirty-eight hours' retention of opaque barium. (Fig. 136, P. J. Briggs.)

B.—DIAGNOSIS OF THE CAUSE OF INTESTINAL CONSTIPATION.

Intestinal constipation may be due to: (1) *A deficiency of the motor activity of the intestines*; or (2) *The requirement of an excessive force to carry the faeces to the pelvic colon*. In the first group of cases aperients are generally much more effective than in the second; in the latter there may be a history that purgatives are producing less effect than formerly, or that they now completely fail to act, but that enemata still give a more or less satisfactory result. The increased activity of the intestines in their attempt to respond to the excessive demands in the second class often leads to colic.

1. DEFICIENT MOTOR ACTIVITY may be due to:—

a. Weakness of the Intestinal Musculature.—When constipation has existed from infancy, especially if it is present in several members of the family, it is likely to be due to

congenital hypoplasia of the intestinal musculature. Constipation developing gradually as old age approaches is generally due in part to senile intestinal hypoplasia. When constipation occurs in anæmic girls, in cachectic conditions, in rickets, and in fevers, it may generally be assumed to be due to weakness of the intestinal musculature secondary to these conditions.

The constipation of fat people is due in part to the inefficiency of the intestinal musculature resulting from fatty infiltration.

In some of these conditions atony of the colon can be recognized with the X rays by its abnormally large lumen, in addition to the slow passage of faeces (*Figs. 138 and 139*). This is especially likely to follow severe colitis and dysentery.

b. Deficient Reflex Activity of the Intestines.

Insufficient Stimulation of Intestinal Movements. Careful inquiry should be made into the patient's diet and habits, as many cases are due to too little food being taken, or to the food containing too little mechanical or chemical peristaltic stimulus, and some are due to deficient exercise. Other cases result from a 'greedy colon', the absorption of food being unusually complete: in spite of enough food of a sufficiently stimulating character being taken, and in spite of the fact that the abdomen is retracted and no accumulation of faeces can be felt in either the colon or the rectum, yet a very deficient quantity of faeces is excreted. This is the type of case in which benefit results from the use of agar-agar or petroleum. In constipation due to an unsuitable diet or to a greedy colon the stools are generally small, dark, and dry, and smell less strongly than normal. In œsophageal or pyloric obstruction constipation is usual owing to the small quantity of food-residue which reaches the colon. The other symptoms generally prevent a mistake in diagnosis being made; but occasionally in pyloric obstruction the patient complains of nothing but some slight indigestion or weak-

Fig. 138.—Diagram of the normal large intestine. The numbers, in this and the following figure, represent the hours after an opaque meal at which the different parts of the colon are reached. C, Cecum; AC, Ascending colon; HF, Hepatic flexure; SF, Splenic flexure; DC, Descending colon; IC, Iliac colon; PC, Pelvic colon; R, Rectum; U, Umbilicus; P, Pelvis.

Fig. 139.—Post-dysenteric atony and paresis of the colon. Compare the lumen of the colon and the slow passage of faeces through it with *Fig. 138*.

ness in addition to the constipation. The passage of a stomach-tube twelve hours after a large meal, when the stomach should be completely empty, and an X-ray examination, will clear up the diagnosis in doubtful cases.

Deficient Sensibility of the Intestinal Mucous Membrane. This is the probable cause of the constipation when there is a history of excessive tea-drinking or of the long-continued use of large doses of aperients; it is also partly responsible for the constipation associated with colitis.

Depression of the Nervous System. In neurasthenic, hypochondriac, and insane patients, the condition of the nervous system is the chief cause of the constipation which is almost invariably present; but an improper diet is generally an additional factor.

c. Inhibition of the Motor Activity of the Intestines. This group of cases can often be recognized by the fact that sedatives, such as opium and belladonna, give relief, whilst purgatives are required in unusually large doses, and produce an unusual amount of colic unless given with a sedative. The X rays show that the small intestine as well as the colon is traversed slowly; this is unusual in other forms of constipation. Inhibition may be *direct, central, or reflex*.

Direct Inhibition in Lead Poisoning. The diagnosis is suggested by the occupation of the patient, a blue line on his gums, or other symptoms of plumbism (p. 45).

Central Inhibition. A history of a recent shock or worry is obtained.

Reflex Inhibition. Constipation is a frequent symptom of painful diseases of abdominal and pelvic viscera, other than the intestines themselves. It can then be cured only by treating the primary condition, so that it is essential to ascertain the cause of the pain. Constipation is particularly liable to result from disease of the vermiform appendix, female genital organs, stomach, duodenum, and gall-bladder.

d. Irregular Spasmodic Contraction of the Intestine: Spastic Constipation: Enterospasm. When constipation is associated with pain, especially if the pain comes on

in attacks during which the difficulty with the bowels is increased, the possibility that it is due to spasm of the colon must be considered. The pain is situated in the course of the large intestine, most frequently in the iliac and pelvic colon, but occasionally in other parts. The affected part of the colon can generally be felt as a contracted, tender cord, in which scybala may be detected and the narrow lumen can be recognized with the X rays. When the pain is in the right iliac fossa, appendicitis may be simulated; the long duration of the attacks without any pyrexia, the occasional history of similar pain on the opposite

Fig. 149. Skiasgram to show the arrest of bismuth by a malignant stricture of the last 3 or 4 inches of the transverse colon. At the subsequent operation a very hard stricture of this exact portion of the transverse colon was found and excised. The nature of the condition was quite unsuspected until bismuth and the X rays were employed; gastric trouble, possibly an ulcer, was thought probable previously. Male, age 35. T.C., complete arrest of food in transverse colon twenty-seven hours after it was given by mouth. (By Dr. C. Thurstan Holland.)

side, and the contracted condition of the ascending colon and sometimes of the cæcum (though in other cases the cæcum may be distended and tympanitic), are distinctive features of spastic constipation. When the pain is in the left side, a tumour of the descending or iliac colon may be suspected: the long history, the absence of visible or palpable peristalsis and of distention above the contracted part, and the absence of occult blood from the stools, are points which distinguish spastic constipation from cancer of the colon. The possibility of diverticulitis also requires consideration, especially in middle-aged or elderly patients: some pyrexia is often present, irritability of the bladder is common, and a barium enema reveals the presence of numerous diverticula of the iliac and pelvic colon. In cases of spastic constipation the stools should always be examined for mucus, as the spasm, especially when it occurs in neurotic women, is often only a symptom of mucomembranous colic, shreds or membranes of coagulated mucus being passed by the patient (p. 495).

2. CONSTIPATION DUE TO THE REQUIREMENT OF EXCESSIVE FORCE TO CARRY THE FÆCES TO THE PELVIC COLON may be due to :

a. Obstruction by Fæces.—Dry, hard fæces, which require abnormally strong peristalsis to carry them to the pelvic colon, result from : (i) Insufficient consumption of water—a common cause of constipation in women ; (ii) Excessive loss of water by other channels—one cause of the constipation of diabetics, and of individuals who perspire freely and are only constipated in hot weather.

b. Narrowing of the Intestinal Lumen.—

Organic Stricture.—Unless this is due to a palpable tumour it may be very difficult to distinguish from constipation due to less serious causes. More or less colic is generally present, and its situation often gives a clue to the localization of the obstruction. An X-ray examination, when the barium is given by mouth, rarely gives any help in the early stages of the disease, although occasionally the actual narrowing of the intestine is observed

Fig. 141. Skiagram showing diverticula of the pelvic colon seen after administering an opaque enema.
By Dr. P. J. Briggs.)

and stasis occurs in the proximal portion of the bowel (*Fig. 140*). Much more valuable information can be gained by the administration of a barium enema. Six ounces of barium sulphate are suspended in a pint and a half of water to which has been added an ounce and a half of acacia mucilage. The fluid is run slowly into the bowel from a funnel at a pressure of one foot. In normal individuals some of it reaches the cæcum almost immediately, but except in the early stages of organic obstruction the passage is more or less obstructed at the seat of a stricture, owing apparently to a superadded spasm.

Non-malignant strictures of the colon are rare, except in connection with diverticulitis. If there is a history of tuberculous or dysenteric ulceration, the possibility of obstruction due to cicatrization should be considered, though this is a very unusual occurrence. Hyperplastic tuberculous infiltration of the intestine, especially of the cæcum, causes obstruction, but the tumour present is difficult to distinguish from cancer. Obstruction to the iliac or pelvic colon may follow the pericolicitis which results from the inflammation

of *diverticula*. If a vesico-colic fistula develops in association with chronic constipation, it should be remembered that pericolicitis due to ulceration of diverticula is a more frequent cause of this condition than is cancer (*Fig. 141*).

Organic stricture of the colon is most commonly due to *cancer*. The possibility of cancer should always be considered when an individual above the age of forty, whose bowels have been regular previously, develops constipation of increasing severity without change of diet or habits, or when a patient who is habitually constipated becomes more so without obvious reason. The constipation is at first intermittent and may alternate with diarrhœa, or rather with a frequent desire to go to stool without effectual evacuation ; drugs become steadily less effective, and enemata, which at first give greater relief than drugs, also lose their effect slowly. Frequently no tumour is palpable, but an examination under an anæsthetic reveals the presence of one in many doubtful cases. The tumour may vary in size, and even disappear after the bowels have been opened well, because a mass of fæces may become impacted above a cancerous stricture which is itself impalpable. Hence, although the presence of a tumour is an important aid in diagnosis, its absence or disappearance does not exclude the possibility of cancer ; only when its disappearance under treatment is accompanied by complete and lasting cure of all symptoms can cancer be excluded. The tumour is hard, and cannot be altered in shape by pressure, as is the case with fæcal tumours. Slight attacks of colic occur frequently, but they are not

often severe until the obstruction is almost complete; the colic may be accompanied by visible and palpable peristalsis and spasmodic contractions of the intestine. The latter is a most important sign, as it never occurs in colic associated with lead-poisoning or colitis, and very rarely with obstruction due to faecal impaction. Progressive loss of weight and strength, anorexia, and anemia are late symptoms, and it is important to make a correct diagnosis before they have appeared. The obvious presence of blood in the faeces is an important symptom, but it is often absent. Much more frequently traces are found which are only recognizable by chemical tests (p. 104). In the absence of hemorrhoids and of haemorrhage from the mouth, throat, or nose, the presence of 'occult' blood in the faeces is strong evidence that ulceration is present in the stomach or intestines: when symptoms pointing to gastric or duodenal ulcer and gastric carcinoma are absent, and constipation is present, a suspicion of cancer of the intestine receives important confirmation. In doubtful cases a sigmoidoscopic examination should be made, as cancer is much more common in the rectum and pelvic colon—which alone can be investigated by this method—than in any other part of the intestine. X-ray examination after the skilled administration of a barium enema is frequently of great help, not only in diagnosing the existence of cancerous stenosis, but also in locating its precise site (*Figs. 142-144*).

Fig. 142. Skiagram taken after a bismuth meal in a case of carcinoma of the transverse colon just beyond the hepatic flexure. A, Site of the new growth.

Fig. 143.—Skiagram showing a distended descending colon in a case in which a carcinomatous growth on the proximal side of the splenic flexure obstructed the barium enema. (*By Dr. P. J. Briggs.*)

A *kink* of the colon is a very unusual cause of constipation. It is sometimes partly responsible for the constipation which is almost always present in visceroptosis. Adhesions should be suspected when an attack of localized peritonitis, due particularly to disease of the female genital organs, appendicitis, or leakage from a gastric or duodenal ulcer, is followed by constipation. An X-ray examination should, however, always be made before advising surgical treatment, as, in the vast majority of cases, even if adhesions are present they have nothing to do with the constipation. The X rays show whether the delay takes place in the neighbourhood of the supposed adhesions, and the presence or absence of adhesions can also be ascertained by seeing how movable the colon is, and whether the two limbs of the various flexures can be separated from each other.

Though the primary cause of *Hirschsprung's disease* is achalasia of the pelvi-rectal or anal sphincter, in the former variety a kink is also produced after the dilatation has

reached a certain degree by the overhanging of the dilated pelvic colon over the undilated rectum (*Fig. 145*). There is always a history of constipation dating from the first few

Fig. 144.—Skiagraph from a case of carcinoma near the end of the pelvic colon which obstructed a barium enema at O. T, Enema tube. (*Fig. 10, P. J. Brooks.*)

months of life, although sometimes the bowels may be opened daily but insufficiently. Soon after birth the abdomen becomes greatly enlarged, the size varying from time to time. The outline of the distended colon can be seen, and peristalsis is often visible. The abdomen finally becomes enormous: it is then tense and tympanitic. Attacks of obstruction are liable to occur, and death takes place most frequently between the ages of three and eight.

If a *large abdominal tumour* is present, constipation may be due to its pressure on the colon.

Chronic intussusception may cause symptoms similar to those produced by a stricture; attacks of colic accompanied by visible peristalsis occur with increasing frequency and severity, and they are often brought on by food or aperients. An intussusception may be suspected in a patient not yet of the cancer age when a sausage-shaped tumour is palpable, especially if blood and mucus are passed at frequent intervals. In one-third of the cases the apex of the intussusception can be felt on rectal examination.

C.—DIAGNOSIS OF THE CAUSE OF DYSCHÆZIA.

Dyschæzia is due to a want of proper proportion between the power of expelling the fæces from the pelvic colon and rectum, and the force required to do this completely. It may therefore be due to: (1) *Inefficient Defæcation*; or (2) *An Obstacle to Efficient Defæcation*.

1. INEFFICIENT DEFÆCATION may be due to:

a. Weakness of the Voluntary Muscles of Defæcation. This should be suspected when constipation dates from pregnancy, or is associated with ascites, large abdominal tumours, or obesity. It is often easy to ascertain the condition of the abdominal muscles by simple palpation in the horizontal position; the discovery of a very movable kidney or a dropped liver would also suggest that the abdominal muscles are weak. The patient should next be told to raise the head from the couch; the recti muscles contract and their length can be ascertained, and any separation between them recognized. Finally, the patient should be examined standing up; bulging of the abdomen below the umbilicus (*Fig. 146*) shows that visceropptosis is present and that the abdominal muscles are weak. The patient often complains of abdominal discomfort, which is relieved by lying down or by pressing the lower part of the abdomen upwards. In all cases in which a woman, whose bowels have previously been regular, becomes constipated after the birth of a child, the condition of the pelvic floor should be investigated, as well as that of the abdominal wall. The anus is normally slightly retracted; the retraction is increased and the anus moves slightly forward when the levator ani muscles are contracted by making the movement which is required when it is attempted to restrain a commencing defæcation. If they are weak, the retraction in the condition of rest is

Fig. 145.—Colon in a case of Hirschsprung's disease. AC, Ascending colon; TC, Transverse colon; DC, Descending colon; IC, Iliac colon; PC, Loop of pelvic colon; R, Rectum; K, Kink at pelvic-rectal junction. The dotted line represents the costal margins.

absent or diminished, and on contracting the levator ani muscles, the retraction and forward movements are slight or absent. On straining, the whole perineum projects much further than it should do, and in severe cases the uterus may be more or less prolapsed: in such cases no further evidence is required to show that the dyschezia is partly due to weakness of the levator ani muscles.

When constipation is present in asthmatic or very emphysematous people, it is partly due to the fact that the great rise in intra-abdominal pressure required in defaecation cannot be produced by contracting the diaphragm, as the latter is already almost as low as it can go.

b. Habitual Disregard of the Call to Defaecation.—When dyschezia is not associated with weakness of the muscles of the abdominal wall or pelvic floor, the history will generally show that it has resulted from habitual disregard of the call to defaecation—a very common cause in girls, and a not uncommon one in schoolboys and business men, who allow themselves too little time between getting up and beginning the day's work. The call is also often neglected if for any reason defaecation is painful.

c. Unfavourable Posture during Defaecation.—Inquiry should be made as to the height of the seat in the water-closet, as when this is too high it is impossible to assume the proper crouching position, and defaecation may consequently be inefficient.

Weakness of the voluntary muscles of defaecation, habitual disregard of the call, and the assumption of an unsuitable position during the act, all lead to the same results—the loss of the defaecation reflex, and atony and paresis of the musculature of the pelvic colon and rectum. The loss of the defaecation reflex is shown by the fact that the patient never experiences a desire to defaecate, even when examination shows that the rectum is full of faeces. The atony of the rectum is shown by its abnormally large size and the very slight resistance offered when the finger presses upon its walls; the atony of the pelvic colon is shown by the abnormally large shadow it forms when examined with the X rays. The paresis of the pelvic colon and rectum is shown by the patient's inability to defaecate by an effort of will when the rectum is full of faeces.

d. Primary Weakness of the Defaecation Reflex.

This is sometimes the cause of constipation in infants:

it is probably the case when defaecation occurs on exaggerating the natural stimulus by the mechanical effect of the introduction of a finger into the rectum, or by the combined mechanical and chemical effect of the introduction of a piece of soap.

e. Organic Nervous Diseases.—When constipation occurs in the course of organic nervous diseases, such as *tuberculosis dorsalis*, *myelitis*, or *meningitis*, it is due to disturbance in the defaecation centre in the lumbosacral cord or the tracts connecting it with the brain. When constipation and difficulty in micturition appear simultaneously the possibility of some organic nervous disease should be considered, even if no other symptoms are present.

f. Hysteria. When dyschezia occurs in nervous individuals it is often due to the patient having suggested to himself that he cannot open his bowels at all, or unless he takes a purgative or an enema. The diagnosis can be confirmed by the result of treatment: if such a patient can be persuaded after a thorough examination that there is really no reason whatever why he should not obtain a daily action of the bowels without artificial aid, he will have no difficulty in curing himself at once.

2. OBSTACLES TO EFFICIENT DEFECATION may be due to:

a. Hard and Bulky Faeces. When the faeces are abnormally hard as a result of intestinal constipation or of the excessive loss of fluid from diarrhoea, hæmorrhage, or other cause, the force required to expel them may be so great, especially if they are bulky,

Fig. 146. - Visceroptosis.

that dyschezia results. This condition can be recognized easily by a rectal examination, which shows that faeces of abnormal hardness are impacted in the rectum.

b. Spasm of the Sphincter Ani. When defaecation is painful it is rendered difficult as well by reflex spasm of the sphincter ani. The anal canal and rectum should be examined with a proctoscope after the introduction of a cocaine suppository, so that any local cause of the pain, such as an anal ulcer or inflamed hemorrhoids, may be discovered. In the absence of these, the genito-urinary organs should be examined for reflex causes of spasm.

c. Organic Stricture of the Rectum and Anus. In every case of constipation a digital examination of the rectum should be made, and in cases of doubtful origin the rectum and pelvic colon should be examined with a proctoscope and sigmoidoscope. *Congenital narrowness of the anal canal* is recognized easily: it is rare, but may give rise to no symptom until several years after the child is born. *Fibrous stricture of the rectum* is an occasional cause of dyschezia, especially in women: it results from inflammatory infiltration of the submucous tissue secondary to infection of an abrasion of the mucous membrane. The condition is generally painful, and often associated with active inflammation and ulceration: it can be distinguished readily from malignant stricture by means of the proctoscope. *Cancer of the rectum or pelvic colon* is a grave cause of dyschezia: when constipation develops after the age of forty without any obvious cause, especially if it is accompanied by a sense of fullness in the rectum and of incomplete relief after defaecation, by loss of weight and strength, or by discharge of mucus and blood, the possibility of cancer of the rectum should always be considered, and a thorough examination made by the finger, proctoscope, or sigmoidoscope.

d. Pressure on the Rectum from Without. Pressure on the pelvic colon and rectum by a *gravid uterus* always produces some dyschezia. Apart from this the possibility of a pelvic tumour, such as *distended tubes*, *cancer* or *fibroid of the uterus*, and *ovarian tumour*, should be remembered in dyschezia occurring in women, especially if there is any pelvic pain. A retroverted but otherwise normal uterus cannot be regarded as a sufficient explanation of dyschezia.

e. Invagination.—When a constipated patient, whose general health is so good that cancer seems improbable, complains that after defaecation he feels as if something were still present in the rectum, especially if mucus and occasionally a little blood are passed, the dyschezia may be due to obstruction caused by the invagination of the mucous membrane of the upper part of the rectum into the lower part. The condition is generally associated with lumbar pain. The invaginated mucous membrane can be felt on digital examination, especially when the patient strains.

II. ACUTE CONSTIPATION.

Acute constipation may be: (A) *Due to acute intestinal obstruction*: or (B) *A symptom of* (1) *some general disease*, or (2) *some other acute abdominal disease*.

A.—ACUTE INTESTINAL OBSTRUCTION.

1. The following points help in the distinction between acute intestinal obstruction and severe cases of acute constipation of other origin: (i) *Visible and palpable peristalsis* or stiffening of the intestines is never present except in obstruction. (ii) *Vomiting* is never *faeculent*, except occasionally at a very late stage, in non-obstructive cases. (iii) In other conditions the *constipation is incomplete*:—

a. Flatus, and even a small quantity of faeces, may be passed spontaneously.

b. A purgative may give a result: it is, however, very unwise to administer **purgatives** in such cases, but frequently the patients have already tried them on their own responsibility.

c. A rectal examination should always be made. In organic intestinal obstruction the rectum is empty: if it contains faeces there may be obstruction due to faeces, but it is exceedingly rare for this to produce symptoms quite comparable in severity with those due to acute obstruction. With this exception, the presence of any quantity of faeces would show that there was no intestinal obstruction.

d. In doubtful cases two enemata should be given, with an interval of an hour: the first generally brings away a certain amount of faeces, even if obstruction is complete: the second results in the passage of faeces or flatus if there is no complete obstruction,

or if the obstruction is high in the small intestine. If there is complete obstruction the second enema is either retained or escapes unaltered and with abnormally small force.

2. Before considering any other possibility, all the hernial apertures should be examined, even in the absence of local pain, as a *strangulated hernia* gives all the signs of acute intestinal obstruction.

3. The following points should be considered in determining the cause of the acute intestinal obstruction :

i. *Age*. Intestinal obstruction in the newborn is almost invariably due to a *congenital malformation* : as this is generally in the rectum (p. 728) the latter should be examined first, and only after it has been found to be normal should the possibility of congenital obstruction in the duodenum or ileum be considered. In infants the common cause of intestinal obstruction is *intussusception* : at a somewhat older age obstruction may arise in connection with a *Meckel's diverticulum* ; but in children and young adults the most common cause is obstruction by *bands or adhesions* resulting from local peritonitis, due to appendicitis, tuberculous peritonitis, or caseous mesenteric glands. Acute obstruction occurring in an infant or child under ten years of age, in whom there is a history of constipation and abdominal distention dating from soon after birth, is most probably due to *Hirschsprung's disease* (p. 163). After the age of forty the possibility of *cancer* of the colon should always be remembered, and in fat patients, especially women, obstruction by *gall-stones*. In patients over fifty, acquired diverticula of the colon are likely to give rise to acute or chronic *diverticulitis* with symptoms and signs which may be mistaken for cancer.

ii. *History*. A previous attack of appendicitis, or a history of tuberculous peritonitis, or of inflammatory pelvic disease in females, suggests the possibility of obstruction by bands or adhesions ; the same diagnosis should be considered if the patient has some weeks or months before had a strangulated hernia reduced. A history of biliary colic or of the symptoms which may result from cholecystitis indicates that obstruction may be due to impaction of a gall-stone. When acute obstruction follows a period of increasing constipation in middle-aged patients, cancer is probably present.

iii. *State of the Bowels*. The passage of blood and mucus without any faeces in an infant or child is suggestive of an intussusception. In older patients it may be due to cancer. The passage of stools during the early stages, in spite of other evidence of obstruction, indicates that the latter is situated in the small intestine.

iv. *Abdominal Examination*.

a. *Distention*. Great distention generally means that the obstruction is in the colon : if present very soon after the onset of symptoms it is probably due to cancer or volvulus ; if it has been present to a less extent for some time before the onset of acute symptoms, a growth is likely ; but if it has developed very acutely, a volvulus is more probable. In infants and small children great distention suggests Hirschsprung's disease if the abdomen is tympanitic : if it is partially dull, and if free fluid or irregular masses are present, tuberculous peritonitis is the probable diagnosis. Well-marked distention in both flanks suggests origin in the pelvic colon or rectum : if in the right flank only, in the hepatic flexure or transverse colon : if the flanks are comparatively undistended and the central part of the abdomen is most affected, the obstruction is likely to be in the ileum or the caecum : distention is slight when the obstruction is in the duodenum or jejunum.

b. *Visible Peristalsis and Stiffening of the Intestine*. - The position and direction of visible peristalsis and the position of stiffening coils of intestine may show the localization of the obstruction. When a series of more or less parallel contracting coils is visible in the central part of the abdomen, the obstruction is in the small intestine : if it appears to culminate in the right iliac fossa, this is likely to be the seat of disease. Stiffening of a length of intestine, which can be seen to rise up and felt to harden, most often occurs in the colon, and especially when there is a growth near its lower end. The most marked peristalsis and stiffening occur when acute obstruction is a sequel of chronic obstruction ; they may be completely absent in very acute primary cases.

c. *Tumour*. The diagnosis of intussusception can be made with certainty only when the characteristic sausage-shaped tumour situated somewhere in the course of the colon is felt. In acute obstruction due to cancer the tumour is often not palpable, as it is generally hidden by the dilated intestine ; but large tumours are felt sometimes, especially when present in the right or left iliac fossa : the former are generally due to cancer of the

cæcum, the latter to cancer of the iliac colon and inflammatory thickening round acquired diverticula: a condition which may closely simulate cancer. Gall-stones can hardly ever be felt.

v. *Rectal Examination.*—A growth of the rectum can be recognized easily, and sometimes a growth of the pelvic colon can be felt through the front wall of the rectum. In infants, the end of an intussusception may be felt in the lumen of the rectum, and more frequently the tumour can be felt on bimanual examination. Obstruction due to pelvic adhesions can often be recognized by the presence of tender masses and the fixity of some of the pelvic viscera. The presence of more than traces of faeces in the rectum in cases of undoubted obstruction indicates that its situation is probably high up in the small intestine. A very ballooned rectum suggests obstruction high up in the rectum or in the pelvic colon, but this is not an invariable rule.

vi. *Pain.* When the pain is localized, or moves in a definite direction to reach its greatest severity at a certain point, the latter is likely to be near the seat of the obstruction. When the pain is situated in the middle line, the obstruction is probably in the small intestine if it is above the umbilicus, and in the colon if below.

vii. *Vomiting.*—The more frequent the vomiting and the earlier the onset of frequent vomiting, the higher in the intestine is the obstruction likely to be. It is most severe in small intestine obstruction due to bands or internal hernia: its onset is later and its occurrence less frequent and sometimes only after food in cases of growth or volvulus of the colon.

viii. *Borborygmi* are sometimes most marked over the seat of the obstruction.

ix. *Shock and Collapse* are more marked the higher the obstruction. They are also much greater when obstruction is accompanied by strangulation owing to bands or hernia than when strangulation is absent, as with gall-stones and cancer.

B. SYMPTOMATIC.

1. *In Acute General Diseases.*—Constipation beginning acutely is a frequent symptom of a large variety of acute infective and other diseases. It is never so severe that it cannot be overcome by purgatives or enemata, and the other symptoms are so much more striking in the majority of cases that the presence of constipation has little influence in forming a diagnosis.

2. *In Acute Abdominal Conditions.*—Constipation is a marked symptom in most acute abdominal conditions. Other symptoms are often so well marked that the question of intestinal obstruction hardly arises. Thus, the diagnosis can generally be made by the early tenderness and rigidity, its localization, and the early pyrexia in acute peritonitis due to appendicitis or the perforation of a gastric, duodenal, or other ulcer: the characteristic situation and radiation of the pain in renal and biliary colic, and the frequent hæmaturia in the former and jaundice in the latter; the presence of a tumour when an ovarian cyst is twisted; the melæna and occasional hæmatemesis, and the presence of a cardiac disease in the heart or abdomen in *mesenteric embolism* and *thrombosis* respectively. Some cases of *acute pancreatitis* are clinically almost indistinguishable from intestinal obstruction, but flatus is generally passed: there may also be a history of biliary colic, and the patient is generally fat, middle-aged, and alcoholic. The diagnosis is seldom made with certainty until the typical fat-necrosis is seen on opening the abdomen. In *lead colic* the constipation is not absolute, and the occupation of the patient and the blue line on the gums suggest the correct diagnosis.

Arthur F. Hurst.

CONTRACTIONS—Athetotic, Choreiform, Fibrillar, Spasmodic, and Tetanic—are all to be defined for present purposes as involuntary contractions occurring in the voluntary muscles.

ATHETOTIC CONTRACTIONS, ATHETOSIS, OR MOBILE SPASM.

Athetosis is a form of involuntary movement affecting the fingers, hands, and wrists most often, less often the toes and feet, and in rare instances the face. It is usually unilateral, but in exceptional cases bilateral—the ‘double athetosis’ of French neurologists. The movements are spontaneous and incessant, and may even continue while the patient is asleep; in other instances they tend to cease, but are started anew or

exaggerated when voluntary movement is attempted. In the hand the movements consist of a succession of slow and serpentine flexions, extensions, hyperextensions, and lateral motions, all combined to cause the fingers and thumb to execute the most curious and complex clutching or spreading movements (*Fig. 147*). The wrist is held more or less flexed: the fingers may move about together, or wander each individually. Analogous movements are observed when athetosis occurs in the lower extremity, or the mouth and face. No great regularity characterizes the motions of athetosis: as a rule they are steady rather than violent: a large amount of voluntary control over the affected parts is retained.

Primary, idiopathic, or primitive athetosis is a rare disease of childhood or of adult life, in which bilateral athetotic contractions first make their appearance in a previously healthy person, either for no particular reason, or after a chill or a nervous shock. It may be associated with epilepsy or insanity. This form appears not to be connected with any gross changes in the nervous system, thus differing from all other conditions in which athetosis is seen.

Athetosis is common in the various *spastic paraplegias of infants and children*, which may be either congenital or acquired: in *congenital cerebral diplegia*, also known as *Little's disease* when the legs are affected chiefly, the nervous structures suffer from an inherited taint (alcoholism, syphilis, insanity), and either fail to develop properly, or degenerate early in life. The onset of Little's disease is gradual, and usually early, but it may be delayed until the child is as much as six or eight years old. The patient is backward or mentally deficient, probably unable to walk, and afflicted with bilateral spastic paralysis. This may affect the legs, the legs and arms, or even the whole body, and may be more marked and more spastic on one side of the body than on the other: speech is defective, optic atrophy common, and the gait is clumsy and stiff, 'cross-legged' or 'scissor'. Involuntary movements occur in the affected members, and are athetotic or choreiform: tremor or intention-tremor is also not infrequent. Although it may not appear for some years after birth, this is really a congenital disorder, and it is to be distinguished, for reasons connected with its pathological anatomy and etiology, from certain other forms of spastic paralysis in infants and children that may closely resemble it clinically. These are the *acquired cerebral paralyses of infants*, the spastic infantile hemiplegias, monoplegias, diplegias, triplegias, paraplegia, that result from more or less localized cerebral injury, inflammation, or hæmorrhage occurring at birth or in infancy. *Porencephaly*, or the occurrence of lacunæ in the tissues of the cortex or brain, may be found in either the congenital or the acquired cerebral paralyses: it is really a post-mortem-room term, and requires no special consideration here.

Fig. 147.—The hand in athetosis.

Acquired spastic paraplegias fall into two categories, according to their etiology:—

1. *Birth palsies*: due to meningeal or cortical hæmorrhage caused by prolonged labour or the use of instruments. Many of these infants have been born prematurely.
2. *Acquired palsies*: due to:—
 - Encephalitis after an acute specific fever, or infective in origin.
 - Polio-encephalitis, the cerebral analogue of acute poliomyelitis in the anterior cornua of the cord.
 - Cerebral embolism.
 - Encephalitis lethargica.
 - Cerebral or meningeal hæmorrhage or thrombosis.

The *birth palsies* are due to injuries received in the process of birth, and the rupture of meningeal or cerebral blood-vessels, with the escape of blood: they develop at once, and the history of the case should make diagnosis easy. The diagnosis of the exact cause of an *acquired spastic paralysis* in an infant or child may be less easy. The paralysis due to *encephalitis* generally appears during the first two or three years of life, but may come

on at almost any age. *Cerebral thrombosis* in children is said to happen oftenest at about the age of six. *Cerebral embolism* is likely to be seen in infants or children with acquired heart disease, the embolus being derived from vegetations on the mitral or aortic valves, or from thrombi that have formed in backwaters of the dilated left auricle or ventricle. These infantile hemiplegias or diplegias are of sudden onset, and are characteristically spastic. Athetotic movements, with or without choreiform contractions, trophic lesions, and tremors, are common in the affected limbs; the children often grow up to exhibit mental defect, imperfect speech, or epilepsy. As a rule, the face is less involved than the arm or leg, and the athetotic movements, confined to the affected parts, may not begin until years after the occurrence of the original cerebral lesion.

Post-hemiplegic athetosis, which cannot be marked off sharply from post-hemiplegic chorea (see p. 171), is an uncommon sequela of hemiplegia in the adult; but common—being seen in about a third of the cases—in the congenital and acquired hemiplegias just considered. In the adult it occurs oftenest when the lesion is situated near the posterior part of the internal capsule or the optic thalamus. These athetotic movements of the extremities have been described already; in the adult they may be combined with choreiform contractions involving the whole arm and shoulder, and the face. The diagnosis should not be difficult, as the history of a stroke will be obtained and the physical signs of a hemiplegia will be present.

CHOREIFORM CONTRACTIONS.

These are similar to the contractions seen in chorea. They are involuntary and inco-ordinated movements, purposive in character, but aimless and ineffective in performance. They are jerky, rapid, and highly irregular; groups of muscles are put into action successively, as if the original intention were given up, or changed, as soon as the complex movement began. They may affect one side of the body only, or both. When mild, they amount to no more than excessive fidgetiness, involving perhaps only the hands and arms, or the hands, arms, and face, in wriggling and grimacing. When severe, they give the patient no rest; he is tossed about, perhaps with the utmost violence, by combined but irregular contractions, in which any of the voluntary muscles may participate. Choreiform contractions bear no resemblance to *tremors*, whether coarse or fine. From *intention-tremors* they are distinguished by the facts that they continue when the patient is at rest, that they are purposive, and resemble ordinary voluntary movements misapplied. From *ataxia* they are distinguished by occurring at rest as well as on attempted movement; the muscular contractions of ataxia are merely inco-ordinated, apparently ill-designed and clumsily executed, types of normal movements.

Choreiform contractions are seen in the following conditions:—

Chorea minor, or St. Vitus's dance; chronic or Huntington's chorea; chorea major, or pandemic chorea; hysteria.

Pre-hemiplegic chorea; post-hemiplegic chorea; spastic paralyses of infants; cortical sclerosis; chorea electrica (Hemoch).

Chorea, chorea minor, acute chorea, or St. Vitus's dance, is a disease of childhood or adolescence, commoner in girls than boys, and closely connected with a history of rheumatism, and with rheumatic endocarditis. Like rheumatism, it is often a family disease; not infrequently one finds that one or two children in a large rheumatic family have had rheumatic fever or rheumatism, another chorea, and another both rheumatic fever and chorea. It is commonly and erroneously held that severe fright may by itself be the cause of an attack of chorea. It may also occur in adults in connection with pregnancy, when it is sometimes of a severe type, and may run on into insanity—*chorea insanienis*. The movements may be confined to one side of the body—hemichorea—but generally affect both sides; the muscles are in general weak, articulation may be interfered with, respiration is often jerky, and the patient is often irritable and emotional. Except in the severest cases the movements cease during sleep; the disease tends to recovery in the course of perhaps two or three months. Mild cases in which the face is most affected may present a certain resemblance to the more chronic and quite unconnected disorder known as *habit spasm, habit chorea, or convulsive tic* (see SPASMODIC CONTRACTIONS, p. 172). A tic is controlled for a time by strong efforts of the will, whereas the movements of

chorea will usually be increased by the concentration of the attention on them; the facial movements of chorea are irregular, representing a succession of various purposive but uncompleted actions, while a tic consists in the repetition of a single definite and purposive movement, originally designed, no doubt, to give relief to some local irritation.

Chronic, degenerative, or Huntington's chorea, is a rare hereditary disease coming on at the age of thirty or forty, associated with slow and difficult articulation and ultimately with insanity. The involuntary movements are slower and more ataxic than are those of acute chorea, and they can often be suppressed for a time by exercise of the will. They affect the extremities and face, are continuous, except during sleep, and are accentuated by excitement, so that at first sight acute chorea may be imitated fairly closely. The diagnosis between this chronic chorea and an acute chorea that has become chronic, as sometimes happens, would turn on the family history, mental symptoms, age at onset, and the course of the disease. Chronic chorea is incurable, and may take twenty years or more to run its course; mental failure occurs early, and is progressive; and a family history of chronic chorea can be obtained.

Chorea major, or pandemic chorea, is an epidemic hysterical manifestation occurring in the more emotional races of Europe under the influence of religious excitement. Choreiform movements are among the less conspicuous of its motor phenomena: it is unknown in the more phlegmatic northern races.

In *hysteria* the motor phenomena are notoriously protean. Should a hysterical patient have had chorea herself, or should she have had the opportunity of observing it in others, she may reproduce its characteristic movements with great accuracy. The diagnosis may be very difficult for a time, particularly if the patient's previous history be not known, and hysteria not suspected. Her temperament will probably lead her to develop other signs or symptoms that suggest the true diagnosis, such as tremors, paralyses, contractures, hemi-anæsthesia of the stocking and glove distribution, exaggeration of the deep reflexes, or attacks of hysterics. Remission of the choreiform movements and of the local symptoms generally may occur when the hysterical patient thinks she is no longer under observation, or when her attention is diverted elsewhere. The hysterical patient simulating chorea or hemichorea is likely to overdo the part.

Choreiform movements may occur in connection with hemiplegia in two forms. *Pre-hemiplegic chorea* has been recorded in a few cases, twitchings or even choreiform movements beginning in the limbs of one side of the body shortly before the onset of an apoplectic stroke. *Post-hemiplegic chorea* is commoner, and more often seen in children than in adults. After a hemiplegia more or less muscular spasm and movements of one kind or another are habitually seen on the affected side of the body. In many patients these movements take the form of tremors, fine or coarse; in others they are athetotic; in others again they are ataxic, occurring only when voluntary movements are attempted; and in yet others they are choreiform. Which of these forms of muscular contraction is likely to occur in any given case it is impossible to say.

Friedreich's ataxy is apt to be associated with choreiform movements of the hands and with nystagmus; but these phenomena are not essential to the disease, which is characterized by spastic paralysis of the legs, absent knee-jerk, extensor plantar reflex and family incidence.

The choreiform movements occurring in the *spastic paraplegias of infants and children* conditions that have been more vaguely described as *cortical sclerosis* on the strength of their post-mortem appearances, are to be regarded as variants of the athetotic contractions already considered above. *Henoch's chorea electrica* is considered below: it is the muscles of the neck and shoulder that are chiefly involved in this rare disorder.

FIBRILLAR CONTRACTIONS.

Fibrillar contractions of the muscles, or fascicular muscular twitchings, are small spontaneous movements visible on the surface of muscles, rhythmical or irregular, involving not the whole muscle, but only single muscular bundles in it. They may be confined to a few of the bundles, or may occur irregularly in any of the bundles composing a muscle. They are almost always too feeble to produce visible movements at the joints: they are increased in fatigue, and when the muscle is mechanically stimulated. Similar, but coarser,

twitchings may be seen in normal muscles when they are over-fatigued, or on exposure to cold. The finest fibrillar contractions are said to occur only in cases of organic disease in the central nervous system. They are seen most freely in muscles that are degenerating or undergoing atrophy, or are shortly about to atrophy, as the result of disease in the lower motor neuron; they cease to appear when the muscle is much wasted. They are most evident in the extremities and tongue.

From a diagnostic point of view, fibrillar contractions are important because for practical purposes they do *not* occur in the *myopathies* or *primary muscular dystrophies* that are due to lesions in the muscles themselves and not in the spinal cord. In only a few recorded cases have these fibrillations been seen in cases of myopathy where lesion of the central nervous system could be excluded. Primary myopathy has become burdened with an elaborate classification and nomenclature; the condition generally has been described as primary progressive myopathy, progressive muscular dystrophy (Erb), idiopathic muscular atrophy and hypertrophy, primitive progressive myopathy, muscular dystrophy, myopathy; special forms of it have been raised to the dignity of 'types', the chief of which are the:

Simple atrophic (Erb)	Facio-scapulo-humeral	Mixed and transitional
Pseudo-hypertrophic	(Landouzy and Dejerine)	(Leyden and Moebius;
Juvenile (Erb)	Distal (Gowers)	Zimmerlin).
	Myotonia atrophica	

Distinctions between these various forms must be sought in special manuals. Their importance for present purposes consists in this—that fibrillary contractions may occur as a rare exception in most of them.

Contrariwise, fibrillar contractions are observed habitually in the course of the *progressive muscular atrophies of neuropathic origin*, variously known under such names as amyotrophic lateral sclerosis (Charcot), progressive bulbar paralysis, progressive muscular atrophy, toxic degeneration of the lower motor neuron, Werdnig-Hoffmann progressive muscular atrophy of infants, according to their special characters. In all of these the lower motor neurons are primarily at fault, exhibiting slow or rapid degeneration; in many cases the upper motor neurons are also affected, either simultaneously, or before or after the lower. Occurring in *infants* or *children*, this neuropathic muscular atrophy is generally of the Werdnig-Hoffmann type, affecting the legs first, and spreading upwards to the body and arms; the hands and feet are affected late, and the deep reflexes vanish. The condition may at first sight resemble rickets, but in rickets there is no real muscular atrophy, the deep reflexes are retained, and fibrillar contractions do not occur. It may be indistinguishable from one of the primary myopathies; but the occurrence of fibrillar contractions would make the diagnosis of neuropathic muscular atrophy the more probable.

In *adults* the disease may conform to one of several types, according to the distribution of the atrophy. In some instances the lower motor neurons of the hand, arm, and neck are attacked, when the CLAW-HAND (p. 141) may result; in others the lower extremities may first show the degeneration. Charcot's amyotrophic lateral sclerosis is characterized by rigidity of the legs combined with atrophy of the muscles of the upper or lower extremities. In making the diagnosis of neuropathic muscular atrophy it must be remembered that the onset is gradual, that fibrillar contractions are present, that the atrophy proceeds *pari passu* with the loss of power, and that sensation and the sphincters are not involved. The electrical changes in the muscles are of assistance, too, the partial REACTION OF DEGENERATION (p. 724) being exhibited; the nerves react normally to faradism, and to galvanism so long as there are muscle-fibres left to respond to the stimulation.

Bulbar paralysis is due to a similar degeneration of some of the cranial lower motor neurons, those mainly affected being the fifth, seventh, ninth, tenth, eleventh, and twelfth. In other cases ophthalmoplegia is observed as well. It is only in the chronic cases of bulbar paralysis that fibrillar contractions are seen, particularly in the tongue, which has been described as looking 'like a bag half full of worms'. The main symptoms are difficulty in articulation, phonation, mastication, and, most of all, in swallowing.

SPASMODIC CONTRACTIONS.

In general parlance, the epithet 'spasmodic' implies suddenness and short duration. These characteristics are not implied by the word as it is used clinically. Hence it is

necessary to distinguish between spasmodic contractions or muscular spasms of three kinds, according as they are : (1) *Short and single*—the muscular twitch ; (2) *Short and repeated*—clonus or clonic spasms ; (3) *Tetanic*—commonly and improperly known as *tonic* spasms ; these are long-sustained.

1. **Single Spasmodic Contractions** of a muscle or group of muscles, over in a fraction of a second, may occur in *normal persons* who are suffering from great fatigue, overwork, or nervous exhaustion. For no apparent reason, and frequently just as the person is going off to sleep, a sudden violent twitch in one or more of the limbs occurs, and wakes him up. In other cases these sudden starts may occur when the patient is resting by day. In *abnormally nervous or excitable patients* such sudden spasms are seen more frequently, and often result from some sudden and unexpected sensory impression—a sound, sight, or touch. The diagnosis of such spasms in nervous or jumpy patients should not be difficult, the affection being very chronic, and no doubt familiar to the patient and the patient's entourage. Coming on suddenly, this jumpiness may be a minor sign of various nervous disorders, such as hysteria, acute chorea, delirium tremens, general paralysis, or Graves' disease.

Single twitches of muscles or of groups of muscles form the outstanding feature of the simpler forms of a series of affections known as *habit spasms* or *spasmodic ties*. A habit spasm consists in the involuntary repetition of some ordinary co-ordinated purposive act. In many instances the tie was at first a natural voluntary act, designed to allay some transient irritation. Thus a blinking tie may have been initiated by the pain caused by a foreign body in the eye, or conjunctivitis ; a sniffing tie by some temporary itching about the nares, or it may be associated with the presence of adenoid growths in the nasopharynx ; a shoulder-shrugging tie by some irritation of the neck due to a tight or rough collar. By voluntary repetition such an act ultimately becomes automatic, when it is spoken of as a habit spasm or tie. These motor ties exist in great variety, oftenest affecting the face, less often the jaws, neck, or limbs : they are so common as to escape comment in their minor manifestations—mannerisms and stereotyped acts being set down merely to 'individuality'. Most ties can be controlled by mental effort with some distress, are increased by emotion, cease during sleep, and are curable only with great difficulty when well established.

More violent and shock-like muscular spasms are seen in the rare condition known as *myoclonus* or *paramyoclonus multiplex*. Myoclonic movements are particularly sudden and violent, occurring bilaterally, or first on one side of the body and then on the other ; they are painless, but may give rise to much inconvenience by their violence. They are increased by emotion and cease during sleep. They may be single, but more often are clonic, repeated perhaps fifty or a hundred times in a minute. In paramyoclonus multiplex there are no mental, sensory, or sphincter changes, and this rare disease is described as both familial and hereditary. Myoclonus is far more commonly observed as a prominent symptom of *epidemic encephalitis*. This disease is so irregular in its onset, course, symptoms, and physical signs that it is impossible to describe it in a few lines. As an inflammation of the central nervous system it is capable of producing disturbance of any of the functions of the brain and even of the spinal cord, the clinical picture varying with the incidence of the process on any particular region. For instance, when the inflammation is most acute in one cerebral hemisphere there may be hemiplegia, hemianæsthesia, or hemianopia. In another case the basal ganglia are chiefly affected, with the result that the patient presents the features of the Parkinsonian syndrome. Other cases are characterized by disturbances of function in the territory of the cranial nerves. Myoclonus may be an early and transitory symptom, or may develop at the height of the disease and persist for months and even many years after the acute illness has disappeared. Epidemic hiccough is possibly an example of mild encephalitis with diaphragmatic myoclonus. As an early symptom myoclonus is common in a particular group of encephalitic patients. These complain of pain in a specified area, often the abdomen, associated with localized muscular contractions which are increased in frequency and violence under the influence of emotion. They may cease after a few days or persist with gradually decreasing severity for many years. In certain rare forms of *epilepsy*, the so-called myoclonic epilepsy, these paroxysmal, asynchronous, bilateral lightning-like movements have been recorded ; the diagnosis will be easy here, as the patient exhibits the phenomena of major epilepsy—loss

of consciousness, relaxation of the sphincters, etc.—in addition to the sudden and forcible myoclonic movements. In certain cases of *minor epilepsy*, or *petit mal*, the affection may take the form of spasmodic twitches of the muscles of a limb, or of the face, associated with a brief absent-mindedness or a few seconds of loss of consciousness without loss of automatic control over the body generally. *Regional jerks* are common manifestations of epilepsy and are of great diagnostic importance in that they may precede the onset of any major or minor attack by months or years. They consist in sudden violent jerks affecting a limb and frequently occur when the patient is in bed in the early morning or when he is dressing. The jerk of an arm may fling the brush from his hand to the other end of the room, or a similar spasm in a leg may upset his balance and cause him to fall.

2. Clonic Spasmodic Contractions. clonic spasms, or clonus, are in reality interrupted tetanic contractions, consisting in rhythmical and more or less rapid repetitions of the single brief muscular spasm or twitch. A typical clonus of muscles in the arms or legs may often be produced in health by the adoption and maintenance of some strained position. Thus ankle-clonus is soon produced if a normal person sits in a chair and strains the heels up while the toes are held pressing on the floor.

Pathologically, clonic spasms are seen typically in the second or clonic stage of *major epilepsy*, where they succeed the initial tetanic (or tonic) stage. Here they are universal and bilateral as a rule, although one side of the body may be involved more than the other, or the arms more than the legs. Consciousness is lost, and the sphincters are often relaxed. Mild and limited clonic spasms of a few muscular groups, without loss of consciousness and lasting for only a few seconds, may be seen in patients with major epilepsy, and are often described by them as 'warnings'. Such attacks are identical with those of minor epilepsy. In certain epileptic patients they seem to be to some extent under control, so that their threatened onset can be prevented if the patient can sit or lie down, for example, or can press on or constrict the limb in which the spasms are about to appear. The diagnosis of *hystero-epilepsy* is sometimes made in these patients; but the term is not a good one, and is often misleading. Very similar convulsive seizures may be met with in patients with chronic nephritis (*uræmic convulsions*) and in pregnant women (*eclampsia*). The clonic stage of epilepsy may be imitated unconsciously by patients with hysteria, or frankly mimicked by the malingerer. In *hysteria* the onset of the fit is gradual, not sudden; consciousness is impaired, not lost; the pupil reacts to light, and is not immobile as in epilepsy; screaming and purposive movements occur throughout, and the fit is often protracted; the sphincters are not relaxed, and the tongue is not bitten. The *maligner* is red and heated by the effort of producing the clonic spasms, his consciousness is fully preserved, and he reacts to painful stimuli that leave the epileptic unmoved. Both the hysterical patient and the malingerer show quivering of the eyelids, and are likely to resist attempts to open the eyes.

In *Jacksonian epilepsy*, clonic convulsions occur without loss of consciousness; they are usually unilateral, starting in some given muscle and spreading thence by a regular 'march' to the rest of the limb in which the twitchings begin, thence to the other limb of the same side until both limbs or half the body are convulsed. Transient paresis from exhaustion may be noted afterwards in the affected muscles. In severe or long-established cases the whole body may be convulsed, or a tetanic stage may occur after the clonus; in these instances consciousness may be lost. Jacksonian or focal epilepsy may result from any form of local irritation of the motor cortex—trauma, hæmorrhage, new growth, the effects of syphilis, chronic inflammation, or encephalitis lethargica.

As the names imply, the very rare conditions known as *myoclonus* and *paramyoclonus multiplex* exhibit typical clonic contractions. The clonus occurs in single muscles or muscle-groups, such as the biceps and supinator longus, the quadriceps femoris and semitendinosus; rarely in the face: from 50 to 150 contractions a minute may occur. *Henoch's chorea electrica* is the same as myoclonus. It is said that animals from which the parathyroid glands have been removed may exhibit identical spasms. Clonic spasms of the neck muscles, particularly the sternomastoids, are common in *torticollis* or wry-neck.

3. Tetanic Contractions, tetanic or tonic spasms. Physiologists and clinicians both make use of the two terms 'tetanic' and 'tonic', but unfortunately employ them in different senses. Physiological 'tetanus' is the apparently steady state of muscular contraction exhibited by the voluntary muscle at work, maintained by the fusion of separate muscular

twitches or spasms due to a rapid succession of nervous stimuli. It may be seen in a single muscle or in many together. Clinically, however, 'tetanus' or 'tetanic contractions' have come to be associated with pain, besides being of some duration, and the terms are used only when a large number of muscles are involved simultaneously; tetanus of a single muscle is referred to clinically as a CRAMP (p. 188), although it may occur in cases of true infection 'tetanus'. To the physiologist, the normal resting muscle is already in a state of 'tonic contraction', and exhibits 'tonus'. This muscle-tone is maintained partly by local or peripheral stimulation (mechanical tension, the venosity of the blood, drugs such as digitalis or veratria), and partly by nervous impulses that reach the muscles more or less continuously from the motor neurons of the central nervous system. This central element of muscular tonus is really of reflex origin and associated with posture, the maintenance of an attitude; the motor impulses descending in answer to ascending impulses received by the central nervous system from the muscles and joints concerned. But the clinician applies the terms 'tonus' and 'tonic contractions' to the severe and pathological muscular contractions seen, for example, in the first stage of major epilepsy, which are physiologically and scientifically speaking tetanic, not tonic. This clinical misuse of the word 'tonic' is well-established and time-honoured, but only serves to promote confusion. The terms 'tonic spasm' and 'tonic contraction' should be reserved for states of muscle-tone that are raised only within physiological limits, and are not pathological. The contractions or spasms that the clinician calls 'tonic' are almost always pathological, and in the interests of uniformity should be described as 'tetanic', not 'tonic'. Exaggerated states of physiological tone and the milder degrees of pathologically heightened muscular tonicity are described clinically as spastic states or spasticity, falling short of tetanus in degree, and differing from both tetanus and cramp by being painless. They are detailed under the heading CONTRACTIONS (p. 177).

Typical tetanic (or tonic) spasms are seen in *tetanus*. Here the patient has become infected by *Bacillus tetani* through some known or unknown wound. He first notices stiffness of the neck and jaws; soon increasing tetanic spasm of the muscles of mastication brings on trismus or lockjaw. Spasm of the facial muscles next brings on the painful grin known as the *risus sardonius*, and presently paroxysmal tetanic spasms of great violence occur in practically all the voluntary muscles, although in mild cases in children the spasm may proceed no further than the muscles of the face. If the spasms are strongest in the extensors of the back, the body is arched backwards till, perhaps, the heels touch the head (opisthotonus). If the flexors contract most powerfully, the body is bent forwards (emprosthotonus); in some cases the body remains straight and stiff (orthotonus) when the flexors and extensors are balanced. These acutely painful paroxysms last for perhaps a few seconds, and recur at varying intervals on any kind of stimulation; they may cause death by asphyxia or heart failure. In the intervals between them a milder but still painful tetanic (the so-called tonic) contraction of the muscles is maintained; or, in milder cases, nothing more than an exaggerated physiological muscle-tone. In mild or chronic cases of tetanus the signs and symptoms will be far less severe than those described above; but trismus and painful muscular contractions will still occur. In some chronic cases the chief sign may be a recurring but transient risus sardonius, perhaps with some stiffness of the neck; not a few of these patients have been treated for *habit spasm* or *hysterical grimacing* for a time, until the suspicion of tetanus arose, or spread of the tetanic spasms to the trunk-muscles made the diagnosis more obvious. The diagnosis of tetanus may have to be made in other instances from *impacted wisdom tooth*; or from *muscular rheumatism*, which may cause stiff-neck but is hardly likely to set up trismus; or from *spinal meningitis*, in which there is fever, while the tetanic spasms occur on exertion, and do not primarily affect the muscles of the jaws, and great pain is felt on moving the head and neck; or from inflammation in the joint of the mandible.

In *strychnine poisoning* trismus is absent or occurs very late, the extremities are first and most markedly affected, the muscles are quite relaxed between the paroxysms, and the symptoms develop rapidly within an hour or two of the administration of the drug. In *tetany* (pp. 2, 189) the distribution and duration of the tetanic contractions should suffice to prevent any confusion with tetanus. In *hydrophobia* there should be a history of a bite by some animal, most often a dog; mental symptoms are prominent, and the

spasms affect the muscles of respiration and deglutition most, while trismus is absent. In *hysteria* a patient may exhibit trismus, tetanic spasms, and opisthotonus; but no true picture of tetanus will be presented, and other evidences of hysteria will be found on examining the patient, or will develop if the case be kept under observation.

SPASTICITY OR SPASTIC STATES.

These terms are applied to those parts of the musculature which are more or less permanently affected by a pathological increase of tone, resulting from lesions of the upper motor neurons, with or without other efferent tracts in the central nervous system. In all spastic conditions the muscular tone is unequally distributed, with the consequence that the part affected tends to adopt and maintain a certain posture. In ordinary cases of hemiplegia resulting from a lesion of the internal capsule the affected upper limb will gradually develop flexor spasticity. The upper arm is adducted and internally rotated at the shoulder, the forearm flexed and pronated at the elbow, the wrist and fingers are flexed. Attempts at passively altering the position are met by an increase of tone in the hypertonic muscles, and prolonged force may be necessary to overcome this involuntary resistance. In the same patient the affected leg will be in a state of extensor spasticity or spastic extension, with inversion of the foot and adduction at the hip.

In cases of double hemiplegia, such as the cerebral diplegias of children, the lower extremities adopt the same posture, with the result that walking is difficult, cross-legged, or impossible.

Transverse lesions of the spinal cord, due to myelitis, compression by tumours, vertebral caries, or trauma, lead to flexor or extensor rigidity of the limbs and are sometimes associated with flexor spasms capable of causing great pain. Other lesions of the central nervous system, such as tumours in various situations, disseminated sclerosis, combined sclerosis, Friedreich's ataxy, syringomyelia, hamatomyelia, amyotrophic lateral sclerosis, Erb's syphilitic paraplegia, and encephalitis lethargica, may be productive of spasticity affecting the face, trunk, and limbs. In all these cases the spastic condition is accompanied by changes in the reflexes—exaggerated tendon-jerks, diminution of abdominal reflexes, and extensor re-

Fig. 148. A case of Friedreich's ataxy, exhibiting pronounced kyphosis or scolio-kyphosis of the dorsal spine.

sponses on plantar stimulation. In the case of all bilateral lesions there is interference with sphincter control in the form of precipitancy, incontinence, or retention.

Spasticity, of whatever origin, may, in the long run, lead to shortening of muscles and tendons, with joint changes. When this has taken place contracture may be said to be present, but it would be a mistake to apply this term to spastic contraction until such structural changes have been established.

In *Friedreich's disease*, a familial disorder beginning usually between the ages of seven and seventeen, and seen oftenest in males, characterized by ataxia, intention-tremor, nystagmus, and hesitating or syllabic speech, spasticity sets up scoliosis or scolio-kyphosis (Fig. 148), pes varus or equinovarus, and 'main bote'—a deformity of the hand with hyperextension of the terminal phalanges, analogous to talipes in the foot. These deformities are partly due to muscular atrophy, partly (in the case of the foot) to changes in the pyramidal tracts: the heel is drawn up, the dorsum of the foot arched, the sole hollowed out, the toes are flexed at the interphalangeal joints and hyperextended at the metatarsophalangeal; prominent hypertrophy of the extensor longus hallucis has been found.

In *subacute combined degeneration*, spasticity of the lower extremities is a common and early clinical feature. The earliest symptoms are paræsthesia of the hands and feet; but the patient, usually an anæmic adult in the second half of life, presently develops

spasticity in his legs. The limbs tend to draw up as he lies in bed, from flexor spasm; the gait becomes spastic, and walking is difficult or impossible—the condition becoming one of *spastic paraplegia*. The deep reflexes are increased, and Babinski's sign is present; segmental areas of anaesthesia can be made out, and control over the sphincters is weakened. After some months, this spastic stage gives place to flaccidity, control over the sphincters is lost, and the patient rapidly runs downhill. Some of these cases have definite pernicious anaemia; others develop the cord changes first and pernicious anaemia later: others die of the effects of the spinal-cord changes and their results without pernicious anaemia becoming apparent; but there is a definite relationship between pernicious anaemia and at least some cases of combined sclerosis of the cord, and in both there is absence of the hydrochloric acid from the gastric juice.

In cases of *transverse myelitis* or *transverse lesions of the cord*, and in certain cases of *haematomyelia* of insidious onset, in which the haemorrhage perhaps takes place into an already dilated central canal, spasticity with increased deep reflexes, loss of sensation, and loss of control over the sphincters is the rule. The diagnosis is facilitated by the fact that no symptoms occur in parts of the body innervated from above the cord lesion; at the level of the lesion there may be girdle pain and hyperaesthesia.

CONTRACTURES.

In the consideration of spastic states it has been pointed out that contractures may result when rigidity of posture has been long-standing and unopposed by any remedial measures. More commonly contractures develop in cases of damage to the lower motor neurons, either at their origin in the central nervous system or in their course through the peripheral nerves. These contractures arise either from the unbalanced action of the muscles that normally antagonize those that have atrophied, or from late shrinkage of the paralysed muscles themselves; and a spinal curvature may come on from the adoption of some posture that facilitates locomotion or the occupations of life when the spinal muscles are intact. Acute and chronic poliomyelitis, neuritis, and lesions of the nerves have to be discussed in this connection. *Acute poliomyelitis*, or infantile paralysis (*Fig. 149*), begins suddenly with malaise, pains, and an acute febrile attack; flaccid paralysis appears early, and contractures begin to show themselves within a few months. The limbs are the parts most involved, isolated muscles or groups of muscles being paralysed; and it should be noted that the paralysis is distributed in accordance with the nuclear grouping of the muscles in the anterior cornual regions of the cord. Sensibility is not affected, and after the first few days there is no disturbance of sphincter control. If many muscles in a limb are paralysed, its growth is much impaired. Contractures are less common in *chronic poliomyelitis* and the various forms of *progressive muscular atrophy of neuropathic origin*, the hands and feet being mainly involved, with the production of various forms of club-foot and claw-hand; fibrillar contractions can be seen in the degenerating muscles, provided that they are not covered too thickly with subcutaneous tissue. The onset is insidious, and the disease occurs most often in middle age; the commonest type is that in which the hands are first and most involved, but in other cases the legs, and in others the upper arm and shoulder, first give evidence of the disease. Contractures are more frequent in *alcoholic neuritis* of the motor type, and also in *arsenical neuritis*, talipes equinovarus or flexor contracture of the wrist, with excessive muscular hyperaesthesia, being noted (*Fig. 150*);

Fig. 149. Bilateral talipes equinovarus in a case of infantile paralysis. (*By Dr. P. W. Saunders.*)

such deformities are rare in other forms of neuritis, such as those due to lead, diabetes, influenza, diphtheria, etc. Secondary contracture of the muscles on the affected side in *Bell's facial paralysis* may occur, and give rise to the impression that the sound side of the face is paralysed while the face is at rest, for the face as a whole is pulled over to the affected side (*Fig. 465*, p. 604): on voluntary movement, however, the healthy

side will be found to move normally, while the paralysed side remains comparatively still. Contractures usually follow severe *injury of nerves* unless appropriate measures are taken to prevent them.

Contractures from disuse may occur in otherwise healthy subjects who for any reason may have been kept too long in one position. Patients who have lain on their backs in bed for long periods may have a temporary talipes equinus when they get up—a contracture due to the weight of the bedclothes resting on the toes and keeping the feet extended.

Fractured or injured limbs that have

Fig. 150.—Bilateral foot-drop (talipes equinus) in a case of peripheral neuritis. (By Dr. P. W. Saunders.)

been splinted and kept too long in one position often exhibit contractures when the splints are removed (e.g., Volkmann's ischaemic contracture of the forearm, *Fig. 151*). In some cases the contracture is due to fixation of the muscles, tendons, or muscle-sheaths by inflammatory products that have become organized, in others to adhesions or bony deposits that have formed in or about the joints, while in others mere disuse, without inflammatory changes, may underlie these contractures: all of these would be avoided by the timely use of massage and movement.

Paralyses occur in perhaps 25 per cent of all patients with *hysteria*, in two main types: the rarer flaccid, the commoner spastic, and often marked enough to produce active contracture. In hysterical contracture the affected muscles are not wasted except in severe cases of long duration: the deep reflexes are increased: a spurious ankle-clonus may be present: but Babinski's sign is not observed. The limbs are most affected (hemi-, mono-, or paraplegia), less often the muscles of the face, eyelids, lips, or tongue. Certain attitudes are characteristic of hysterical paralyses: the elbows, wrists, and fingers are kept flexed, the arms adducted: the hip and knee are extended, and the foot is held in a position of talipes equinovarus: ptosis

is simulated by spasm of the orbicularis palpebrarum: oedema by contracture of the sternomastoid. In the less severe cases the stiffness and paresis are neither complete nor marked enough for the condition to be referred to as a contracture. The deformity produced is the result of active muscular spasm, and in severe cases it cannot be overcome by the application of mechanical force. The contracture often persists during sleep, and is abolished only by deep anaesthesia—a character distinguishing hysterical contractures from those due to organic disease. Hysterical contractures often last

for months, or even years, and, in cases of long standing, muscular atrophy and structural changes about the joints may establish permanent passive contracture from disuse. Highly characteristic of hysterical contracture is the patient's use of antagonistic muscles to prevent passive or active correction of the deformity exhibited. If, for example, the arm is semiflexed by contracture of the biceps, the triceps can be felt to contract and resist the movement when the attempt is made to flex the arm further. A similar contraction of the triceps can be felt or seen if the patient is asked to bend the

Fig. 151. Volkmann's ischaemic paralysis following the use of an anterior splint for fracture of the bones of the forearm. Note the clenched fingers and the trophic sore on the back of the hand. (Photograph supplied by Mr. R. P. Roelands.)

joint herself; with the result that the joint remains unmoved, although all signs of great effort to bend the arm may be displayed. Pain and tenderness in the contracted muscles are usual; and other hysterical stigmata such as hemianæsthesia, paræsthesia, clavus or globus hystericus, and the hysterical temperament generally, will not be wanting. Special forms of hysterical contracture may give rise to great trouble in diagnosis by imitating definite conditions or diseases. Thus a painful 'hysterical hip' or 'hysterical knee' may pass on from surgeon to surgeon, until one is found to operate upon the normal joint for tuberculous arthritis; hysterical spasm of some of the abdominal muscles may lead to the diagnosis of pregnancy or new growth; pseudocyesis or phantom tumour; hysterical contracture of muscles in the neck or shoulder may be diagnosed as new growth, the palpable tumour vanishing only when the patient has been anesthetized and is on the operating-table awaiting incision.

Torticollis, or wry-neck, in adults, is a disease of unknown origin, very rarely associated with any permanent contracture of the affected muscles. The muscles chiefly involved are those supplied by the spinal accessory nerve. Its clonic variety is easy to diagnose; but where the spasms are tetanic (or tonic) rather than clonic, the diagnosis must be made from such conditions as cervical caries, rheumatic myositis, or deep inflammation in the glands of the neck. *Congenital torticollis* dates from birth, usually affects the right sternomastoid muscle, and is often associated with facial asymmetry when it is perhaps due to congenital defect of the centres in the bulb. The face is smaller on the side of the affected sternomastoid. *Congenital torticollis* is distinguished from the form of wry-neck produced in infants by rupture of the sternomastoid muscle at birth during delivery, by the fact that in the latter a callus is to be felt at the site of the rupture.

Other Contractures are due to affections of the bones, joints, or soft tissues that mechanically obstruct correction of the deformities they produce. The contracted limbs can be straightened only by surgical measures, or by manipulations severe enough to rupture the obstructions.

Fig. 153. An unusual type of Dupuytren's contracture, affecting, not the little and ring fingers, but the middle and index fingers. The cause of this departure was the patient's occupation—namely, that of a coal porter. (By Dr. Ryam.)

Fig. 152. Dupuytren's contracture of the palmar fascia in an early phase; both hands are beginning to be affected, but one more than the other.

Contractures may result from the most varied *local organic diseases* of the affected parts. *Dupuytren's contracture* of the palmar fascia, leading to deformity of the little and ring fingers (Figs. 152, 153), is so characteristic that it can seldom be mistaken. It is prone to occur in gouty subjects and in those whose work entails repeated strain on the palms of their hands, as in the case of coachmen and those who use spades, etc. In diseases of the *joints*, such as rheumatism, rheumatoid arthritis, spondylitis deformans, tuberculosis, gonorrhœa, etc., the patient

may lie in bed or go about for weeks or months in some bent or contorted position that involves the minimum of discomfort; ankylosis of the affected joints often results from the growth of adhesions, eechondroses, or exostoses in and about the edges of the joints, that permanently limit their range of movement. Corresponding shortening will take place in the muscles that are relaxed, and a passive contracture results. The growth of a tumour in or about a joint may produce identical results. Traumatic or

inflammatory lesions about the *muscles* or their *tendons* may establish inflammatory products locally that permanently limit the movements of these structures. Large superficial *scars* due to extensive burns or losses of skin and the superficial tissues, being composed mainly of fibrous tissue, may contract, and so bring about marked contractures (*Fig. 154*).

Spondylitis deformans, a chronic malady of the spinal column (p. 796), often results in contractures and partial ossification of the ligaments and muscles of the back ; and extreme

Fig. 154.—Cicatricial contracture after a burn.
(From Professor Rutledge Morrison's 'Introduction to Surgery'.)

deformity may arise from *myositis ossificans*, a rare but easily diagnosed affection in which the muscles all over the body gradually become rigid from calcification ; the patient has generally been normal up to adult life, and then becomes the subject of acute attacks of pain in various muscles, accompanied by local myositic swelling and some pyrexia ; after the local inflammation subsides, calcium salts are deposited in the site that has been inflamed and the affected muscle becomes stiff and hard. Weeks or months may elapse between successive attacks of this kind, but the number of calcified muscles slowly mounts up, until in extreme instances the patient is rigid almost from head to foot the 'ossified man'.

The diagnosis of the cause of a contracture will obviously depend upon the results of the physical examination of the affected part, and upon the success with which a true history of the onset and course of the case can be elicited.

E. Fairbair Buzzard.

CONVULSIONS or CONVULSIVE SEIZURES, are paroxysms of involuntary muscular contractions. They may be divided into two classes, according as they are *local* or *general* ; *local convulsions* have been considered under the heading **CONTRACTIONS**, **SPASMODIC** (p. 172), and the following account deals mainly with *general convulsions*. The general convulsions without loss of consciousness that constitute **RIGORS** are described under that heading (p. 736) ; with this exception, general convulsions are almost always accompanied by loss of consciousness, excepting in some few cases of partial epilepsy and of hysteria.

In most cases of convulsions, both sides of the body—face, neck, arms, trunk, and legs—are convulsed equally. But it sometimes happens that though their cause is apparently general, the movements are unilateral, or much more marked on one side of the body than the other ; for present purposes such convulsions may still be termed general. Usually convulsions are clonic, less often tetanic or tonic.

'Fits' may be defined roughly as any sudden paroxysms or seizures occurring in the course of any disease. In common usage, however, a 'fit' is a convulsive fit, or fit of convulsions, and if unqualified, the term usually means an epileptic fit, but not always.

Certain clinical features are common to almost all convulsive seizures in which consciousness is lost. If the onset is sudden, as it usually is, the patient is apt to fall down and injure himself unless already recumbent. If the muscles of the mouth and jaws are involved and saliva is secreted freely, the mouth foams ; if the tongue or cheeks are bitten, the foam becomes stained with blood. Clenching of the jaws will make the breathing laboured, stertorous, and ineffectual. If the muscles of respiration are greatly affected, cyanosis, with congestion of the face, neck, and exposed parts, will be observed. The convulsive movements are typically clonic, limited in range, purposeless, and accompanied by more or less rigidity. If the rigidity is marked, the amplitude of the movements will be reduced correspondingly, so that the condition may even become one of stiffness and tetanic (or tonic) spasm. It is characteristic of epilepsy that the fit should consist of a brief tetanic stage followed by a longer stage of clonus ; but convulsive attacks of every sort may occur in epilepsy, and either the tetanic or the clonic stage may be absent or so

brief as to pass unnoticed. Control over the organic reflexes of micturition and defæcation is often lost, the bladder and rectum being emptied involuntarily. As a rule the reflexes cannot be obtained while the convulsions last, and are lost or diminished for some hours after they are over, or are unequal on the two sides of the body. When the fit is over and the patients have recovered consciousness, they often complain of headache and lassitude, showing diminished sensibility to all impressions, mental hebetude, and great sleepiness. Less often, the patient becomes excited or terrified after a fit, or even maniacal, and he may also exhibit automatism for hours or even days : in none of these conditions will he be responsible for his actions. The duration of general convulsions is commonly to be measured in seconds or minutes : but in severe cases they may go on for hours if untreated, and in the status epilepticus may last for days with only brief intermissions. Prolonged convulsions due to any cause may raise the temperature several degrees : when they are unilateral, the temperature is raised more on the affected side than on the other. Albuminuria after a fit is very common, and may last for a day or two : it is by no means necessarily evidence that the fit was uræmic.

The morbid conditions in which *local or partial convulsions*, and in rarer instances *general convulsions* also, occur without loss of consciousness, have been considered under CONTRACTIONS, SPASMODIC (p. 172), but may be recapitulated :—

Fatigue	Hysteria	Hydrophobia
Nervous exhaustion	Jacksonian epilepsy	Strychnine poisoning
Habit spasm	Chorea electrica (Hénoch)	Camphor poisoning
Spasmodic tic	Tetany	Malingering.
Myoclonus	Tetanus	

The convulsions commonly accompanied by loss of consciousness may be grouped under the following heads :

1. General Convulsions of Infants and Children seen in :—

Hereditary syphilis	Meningitis	Idiocy
Congenital heart disease	Drug poisoning	Rickets
Cerebral paralysis	Enlarged thymus	Epilepsy, minor and major.
Onset of acute fevers		

2. General Convulsions of Adolescents and Adults, seen in :—

Epilepsy, minor and major	Stokes-Adams' disease	General paralysis
Jacksonian epilepsy	Saturnine encephalopathy	Chronic alcoholism
Epileptiform convulsions :	Cerebral lesions :—	Cerebral syphilis
Uræmia	Apoplexy	Disseminated sclerosis
Pregnancy	Meningitis	Hysteria
Severe heart disease	Encephalitis	Malingering.
Asphyxia	Intracranial growth	

3. Unilateral Convulsions, seen in :—

Apoplexy	Meningitis	Jacksonian epilepsy
Intracranial growth	Epilepsy, major and minor	Disseminated sclerosis.

1. General Convulsions of Infants and Children. Among the commonest of all convulsive seizures are those occurring in children of tender age, known as *infantile convulsions*. The sexes are affected equally : about a third of the cases take place during the first year of life, two-thirds during the first two years : and they are rare, apart from epilepsy, after the age of five or six. They are of more serious import in infants under six months than in older children, and also in anæmic and weakly infants. In *hereditary syphilis* convulsions may prove fatal during the first week of life. For the rest, in about half the patients *rickets* is the predisposing cause : in many of the others some local irritation, such as inflammation of the gums in *dentition*, *diseases of the nose or ears*, the presence of *irritating food* or *worms* in the intestine, renal or vesical *calculus*, or *phimosis*, can be found : while convulsions at the onset of *acute infectious diseases*, such as scarlet fever, pneumonia, measles, whooping-cough, or during their course, and in *nephritis*, are not infrequent. Overdosing with *drugs*—strychnine, atropine, santonin, morphia—or with *alcohol*, may bring on convulsions. Fright and over-strung emotions are included among the causes of infantile convulsions ; inheritance, the neurotic or neuropathic taint, is responsible for some. They occur in children with enlargement of the thymus gland, the so-called *status lymphaticus*, and

in these not infrequently a fit has a fatal issue. Finally, fits in any child may be early evidence of *epilepsy*, or of organic disease of the brain. Their diagnosis demands a very careful examination of the child, and also of its diet and the hygiene of its daily life. They may be due to *congenital heart disease*, when there will be enlargement of the heart, a cardiac murmur or murmurs, and some degree of cyanosis. In children with organic disease of the brain (*porencephalus*, *congenital or acquired cerebral paralysis*, *spastic paraplegia*, etc.) there will be paralysis, spasm, and muscular atrophy, and probably mental defect. If the convulsions are due to the *onset of some acute infectious disorder*, they will come on suddenly in a child previously well, and will be accompanied by fever and followed by the characteristic rash. Similar convulsions and fever may occur in *meningitis*, usually towards the end of the disease. They are not rare in *whooping-cough*, particularly in rachitic infants, being precipitated by the asphyxia resulting from the whooping, and occasionally causing death. The diagnosis of fits due to *drugs or alcohol*, taken either by the child, or by the mother if the child is being suckled, will depend upon obtaining an adequate history of the case. In what way *enlargement of the thymus* brings about convulsions is not known: the condition is fortunately rare, and is hardly ever diagnosed during life. The fits occurring in *hydrocephalus* and the various degrees of *mental defect* need only be mentioned.

It is to *rickets* that one must look for the explanation of most convulsions occurring between the ages of three months and four or five years. The nervous system is unstable in all young children, the power of cerebral inhibition not being acquired for several years. In rickets this instability is much increased, and finds expression in irritability, fits of screaming, restlessness, inability to sleep well at night, and in the more serious troubles of tetany, laryngismus stridulus, and convulsions—a state of affairs sometimes designated *spasmophilia*: any child with fits should be examined for evidence of rickets—exaggerated curvatures in the long bones, the rickety rosary, a Harrison's sulcus on the sides of the chest, the large and bulging rickety head, thinness of the hair on the back of the head (due to head-rolling), a tumid and flaccid abdomen, lateness in the closure of the anterior fontanelle, and very often unhealthy fatness with general muscular debility. Inquiry should be made for other symptoms common in rickets that will come under the observation of the mother or nurse—tenderness of the bones and skull on handling and washing, head-rolling due to tenderness of the skull, sweating about the head in sleep, broken slumber, proneness to gastro-intestinal upsets, constipation and mucous stools or constipation alternating with diarrhoea, unusual liability to coryza and bronchitis, or catching cold. The feeding and hygiene of the child must be gone into: in low life rickets is mainly due to deficiency of fat and protein in the diet, with excess of carbohydrate food, whereas in high life the diet is more likely to err by lack of freshness due to too careful sterilization or to the use of patent foods: rickety children suffer from want of enough exposure to fresh air and sunshine. But if rickets is the main predisposing cause of infantile convulsions, it must be remembered that they may be actually brought on by some secondary exciting cause, such as a gastro-intestinal disturbance with diarrhoea or vomiting, or reflex irritation of any sort. Whether *dentition* is in itself enough to account for convulsions is doubtful, although that 'teething-fits' do occur is one of the things that every woman

Epilepsy is one of the last causes of infantile convulsions that should be thought of, except when the fits occur for the first time in tolerably healthy children more than three or four years old. A bad family history of fits or of insanity would make epilepsy more probable: so would the occurrence of an aura before the fit, and the division of the fit into a tonic and a clonic stage, with biting of the tongue or cheeks. The repetition of fits for which there is no local or general cause such as those described above would be in favour of epilepsy, particularly if the sequence extended over a long period of time. But one fit undoubtedly facilitates the occurrence of another soon afterwards, so that the recurrence of convulsions for a few days or weeks in a rickety child is not enough to justify the diagnosis of epilepsy.

2. General Convulsions of Adolescents and Adults.—The convulsions of *epilepsy*, including both the major and the minor forms, are very variable in extent and duration. In the minor degrees, or *petit mal*, there is usually brief tonic or tetanic spasm, with loss of consciousness, but without clonus or convulsions. In severer cases this is known as *tetanoid*

epilepsy, a tetanic spasm convulsing the patient for some seconds, or even for a minute or two, with risk of death by asphyxia. In *partial epilepsy* the convulsions are confined to part of the body—the face, perhaps, or the arms and face. Midway between minor and major epilepsy comes *epilepsia media*, in which there is muscular spasm of tonic character, without the clonic spasm which follows when the tonic spasm is more severe. In *major epilepsy* the typical picture is as follows: after experiencing an aura or warning of some sort for a few seconds, the patient is seized with a general tetanic spasm, cries out, and falls to the ground, this tetanic or tonic stage lasting for from five to thirty seconds. This then gives place to the clonic stage, or convulsions, with foaming at the mouth, and clonic jactitations that are often unequal on the two sides of the body. After a few minutes the clonus dies away and the patient is left comatose or stupefied, with a headache that is slept off in the course of the next few hours. Consciousness is always lost in true epilepsy; the extent and duration of the convulsions, however, are highly variable, though one may say in general that the longer the fit lasts the less likely is it to be epileptic. The fits of *Jacksonian epilepsy* are rarely generalized. In true epilepsy there is no known organic lesion of the brain; the loss of consciousness and the convulsions are due to some unknown functional disturbance of its action; but apparently identical fits may occur in the course of a number of diseases in which organic lesions are present either in the brain or elsewhere, and to these the name *epileptiform convulsions* is given. They are seen most often in *uræmia*, in which the kidneys are severely diseased and toxæmia results; the patient exhibits the characteristic picture of advanced renal disease, with headache, high blood-pressure, hypertrophied heart, albuminuria, probably retinal changes, and anæmia; or may have a stricture of the urethra or an enlarged prostate with secondary ascending nephritis; or may be the subject of renal tuberculosis perhaps. It must not be forgotten that transient albuminuria is commonly present after fits due to any cause whatever. In the intervals between uræmic convulsions the patient may remain unconscious.

The convulsions occurring in connection with *pregnancy* are known as *eclamptic fits*, the condition as *eclampsia*. The majority of such convulsions come on before labour, some during labour, and 15 or 20 per cent during the first week after parturition; any fits occurring after this are probably due to some cause—uræmia, for example—other than pregnancy or parturition. In many cases the fits occur suddenly and without any warning, or after no more than a brief period of headache or restlessness, or after vomiting. Eclampsia appears to be an auto-intoxication accompanied by a profound disturbance of the protein metabolism; its primary cause is in the placenta. Its diagnosis can rarely be difficult. There is nearly always albuminuria, and some observers regard puerperal eclampsia as one variety of uræmia.

Epileptiform convulsions may occur in *severe heart or lung disease*, and, indeed, in the terminal stages of many disorders, due in part to asphyxia, in part to toxæmia. Like certain obstinate infantile convulsions, they may often be stopped by the administration of oxygen.

In *Stokes-Adams' disease* (p. 108) associated with *heart-block*, epileptiform or apoplectic-form convulsive seizures occur from time to time, no doubt due to the cerebral anæmia resulting from temporary diminution of the heart's rate of action. The radial pulse is habitually slow in this disorder, but becomes suddenly slower at the time of the 'attacks', beating perhaps forty or thirty or even only twenty times to the minute; the cardiac auricles, on the other hand, beat at the normal rate. The patients are usually arteriosclerotic people in the second half of life; their convulsions seen for the first time may readily suggest a diagnosis of apoplexy, but this will be corrected later when it is found that the attack leaves no paralysis or paresis behind it, that similar seizures have occurred before, and that the pulse becomes excessively slow during the seizures.

General convulsions due to direct irritation or disease of the brain may result from a number of *cerebral lesions*, unilateral or bilateral, most commonly the latter; in most of these there will be other signs or symptoms of disease, especially optic neuritis, that should suffice to clear up the diagnosis. Such convulsions may be seen in *meningeal*, *subdural*, or *arachnoid hæmorrhage*; in *meningitis* due to the *B. tuberculosis*, Weichselbaum's *meningococcus*, or other microbes; in *cerebritis*, *encephalitis*, and *encephalitis lethargica*; in congenital anomalies of the brain such as *porencephalus*, *hydrocephalus*, and the abnormalities met with in idiots and mentally defective children generally; and in *cerebral* or

cerebellar abscess, tumour, or aneurysm, when sufficient growth has taken place to raise the intracranial pressure generally. In another group may be placed those cases in which extensive degenerative changes have taken place in the brain: fits are common in the second and third stages of *general paralysis of the insane*, when other signs, such as defective memory and judgement, grandiose ideas, inequality or reflex immobility of the pupils, blurred speech, tremors of the tongue and face, loss or exaggeration of the deep reflexes, and muscular weakness may be looked for; in the insanity of *chronic alcoholism*, with its tremors and inco-ordination, its marked sensory perversions, and its paramnesia or illusions of memory; and in *cerebral syphilis*, where the lesions may be either vascular, gummatous, meningeal, diffuse, or a combination of any or all of these, and the main symptoms are headache, insomnia, attacks of aphasia and hemiplegic or epileptiform convulsions, paralysis of cranial nerves, and dementia in the diffuse cases. *Chronic plumbism* may produce cerebral symptoms of the most varied kind (*saturnine encephalopathy*), from simple headache to acute mania, and amongst the phenomena, convulsions of epileptiform type may be prominent. The diagnosis is based upon the history, the occupation, the other symptoms of lead poisoning (p. 45), and perhaps upon the discovery of lead salts in the urine or in the stools.

Lastly must be mentioned the general convulsions of the hysterical and of malingerers. In *hysteria* the fits are noisy and protracted performances, the movements more or less purposive and quite unlike clonus; the patient becomes red in the face rather than blue or white; consciousness is not lost, attempts to open the eyes are resisted, pressure into the supra-orbital notch causes withdrawal of the head, the sufferer's hand is withdrawn if pressure is made between a nail and its matrix; the sphincters are not relaxed, and the tongue or cheeks are rarely bitten. The convulsions are brought on by some emotional upset, and tend to cease when received unsympathetically. The *malingeringer* may display no little art and skill in his convulsions, which are modelled on those of epilepsy; here again the sufferer is red in the face rather than blue, although he may breathe stertorously, and, with the help of a little soap, foam at the mouth; consciousness is not lost, the corneal reflex is present, the head and hand are withdrawn from painful impressions; the sphincters are not relaxed; perspiration is usual; it is said that in epilepsy, if the hands are clenched, the thumb is buried in the palm, whereas the malingeringer clenches it outside the fingers; on the detection of its character, the simulated fit ends as suddenly as it began.

3. Unilateral Convulsions.—The convulsions in *apoplexy* are habitually limited to one side of the body. The onset of apoplexy, more often gradual than sudden, is generally preceded by headache, dizziness, and tingling or weakness in some part of the body; and it is more marked in cerebral hemorrhage than in embolism or thrombosis. The loss of consciousness comes on earlier and persists longer in cerebral hemorrhage than in the other two conditions. When the convulsions are prominent the case is described as one of *epileptiform apoplexy*. *Cerebral hemorrhage* is commoner in middle life, in persons with high blood-pressure and hypertrophied hearts, and in the subjects of arteriosclerosis; *cerebral embolism* is associated with endocarditis or intracardiac thrombosis, and occurs oftenest in young persons with heart disease; *cerebral thrombosis* is seen in syphilitic patients, and in those with vascular disease, and is characteristically of slow onset after premonitory warnings.

With *cerebral abscess* and *cerebral tumour* convulsions are not very common, and they usually appear only after the diagnosis has been made clear by the occurrence of such cardinal symptoms as headache, vomiting on change of position, optic neuritis (choked disc), and localizing signs pointing to intracranial tumour; but it may happen that an epileptiform fit with unilateral or bilateral convulsions is the first sign that anything is wrong, or at any rate the first thing that makes the patient consult a medical man. The headache that follows a convulsive seizure is likely to be very severe and prolonged. Of the two, *cerebral abscess* is the more likely in patients with chronic suppurative disease of the ear or nose, or of the facial and frontal sinuses. Meningitis—especially *tuberculous meningitis* in its later stages—often exhibits unilateral or bilateral convulsions, squint and other local paralyses, more or less coma or mental apathy, gastro-intestinal symptoms, Cheyne-Stokes breathing, and irregularity of the pulse-rate and temperature; lumbar puncture and examination of the cerebrospinal fluid (p. 382) may be required in establishing the diagnosis and in distinguishing between the tuberculous, the suppurative, and the epidemic cerebrospinal—'spotted fever'—forms.

The unilateral convulsions of *Jacksonian epilepsy* are rarely difficult to diagnose. The patient usually gives a history of head injury, and often a cranial scar or irregularity is to be found. There is no loss of consciousness during the attack, except in very severe and inveterate cases; usually only one limb is involved, and an aura of some sort generally precedes the convulsions, which exhibit a characteristic 'spread' beginning in a single muscle or group of muscles, and spreading thence to the muscles whose cortical areas of representation adjoin that of the muscle first involved. In Jacksonian epilepsy there is almost always an irritative lesion of the motor cortex or its immediate vicinity, due to trauma, syphilitic meningitis, or new growth; paresis or paralysis of the affected muscles follows the convulsions, and in the course of time becomes marked. The 'spread' is frequently characteristic: if the face is involved first, the arm follows, and then the leg; if the hand is attacked first, the convulsions spread up the arm, then to the face, last to the leg. In the severer cases, where the whole side of the patient is convulsed, consciousness is lost, and then the convulsions may become bilateral.

Unilateral convulsions do not occur often in *epilepsy* or *infantile convulsions*, or *epileptiform convulsions*, and when they do there is a danger lest the diagnosis of apoplexy or some focal organic lesion of the brain be made. There is nothing in the character or distribution of the convulsions in these cases to enable a diagnosis to be made, and it is only after they are over, and it is found that no evidence of organic cerebral mischief is left behind, that their functional nature can be established. They are not followed by any permanent paresis, paralysis, or atrophy of the muscles on the affected side. Unilateral convulsions, the so-called 'apoplectiform' convulsions, may occur exceptionally in some of the conditions detailed under Group 2.

In *disseminated sclerosis*, hemiplegic apoplectiform attacks like those seen in general paralysis are not rare, often accompanied by aphasia. These attacks are both transient and recurrent. The patients are likely to exhibit other evidences of disseminated sclerosis—a childish and optimistic mental attitude, optic atrophy, nystagmus, impaired articulation, intention tremor, undue muscular fatigability; the deep reflexes are commonly increased, Babinski's extensor plantar reflex is present, sensation is but little affected, and control over the sphincters is rarely lost until late in the disease.

A. J. Jer-Blake.

CORNEA, ULCERATION OF.—(See ULCERATION OF THE CORNEA, p. 890.)

CORYZA. (See DISCHARGE, NASAL, p. 223.)

COUGH. Cough is a signal that something is irritating the cough centre in the medulla oblongata, or a branch of the vagus nerve, or the phrenic nerve—which has afferent sensory fibres as well as the motor fibres responsible for the movements of the diaphragm—and is, in fact, nature's effort—often ill directed—to remove that something.

The branches of the vagus are as follows:—

(1) A small meningeal branch, of no interest as causing cough, though it may possibly account for vomiting in meningitis; (2) Arnold's branch to the lobule and external meatus of the ear—a cause of cough, though a rare one, due to affections (wax, eczema, etc.) of the external ear; (3) Pharyngeal branch—a frequent source of cough; (4) Superior laryngeal branch—sensory to the base of the tongue, part of the pharynx, and the larynx—a frequent source of cough, with or without visible changes; (5) Inferior laryngeal branch—motor for the action of coughing, not a cause of cough, but of inefficiency and other peculiarities in the act of coughing; (6) Cardiac branches—indirect causes of cough through circulatory failure; (7) Pulmonary branches—concerned in the cough of gross pulmonary or pleural disease; (8) and (9) Œsophageal and pericardial branches—possible but most rare causes; (10) Gastric branches—responsible for the 'stomach cough' of dyspeptics.

The irritants to which the surfaces of the distribution of these nerves are exposed may be classified into: (1) Foreign bodies, e.g., dust, food, tobacco smoke, fumes; (2) Excess of natural secretion; (3) Pressure; (4) Inflammation; (5) Increased irritability, e.g., after influenza or other similar illness, or in nervous subjects—functional cough, or cough neurosis.

In dealing with the treatment, there is no better division of coughs than into those which are helpful and those which are not, and the same division is most useful in arriving

at a diagnosis of the cause of a cough; for if the cough succeeds in its object—the removal of the offending material—we can see, or at least inquire about, its nature, and this will at once give a strong clue to the locality of the irritable point, and very possibly also to the morbid process going on. Hence the first questions to ask a patient with a cough are: “Do you bring anything up?” “What do you bring up?”

Cough without Expectoration.—If the answer to the first question be, “No, the cough is just a troublesome dry cough, with no expectoration at all,” we at once begin to think of the purely reflex coughs produced by an irritant which the cough itself is powerless to remove; and though we may often make a short cut to a diagnosis by other means of investigation or observation of the general condition, the following routine should be followed if no prominent clue offers itself:

1. Examine the external ear for wax, eczema, etc., although these should not be accepted as explaining the cough until other, especially intrathoracic, causes have been excluded.

2. Examine the tonsils, anterior and posterior pillars of the fauces, the pharynx, and the condition of the posterior nares with thorough care; in children chronic infection of the tonsils, especially when associated with adenoids, is responsible for recurrent coughs which may seem to the parents almost incessant—only stopped when the tonsils have been enucleated and the adenoids removed. Tonsillar trouble as a cause of cough is not confined to children, though the chronic septic foci in the lower poles of the superficially normal-looking tonsils may not be detected if the tonsils are not examined with thoroughness in a really good light. Syphilitic pharyngitis may be suggested by the snail-track ulcers on the post-pharyngeal wall, and the diagnosis clinched by finding the Wassermann serum test positive. More serious lesions such as sarcoma or epithelioma of one tonsil, epithelioma of the pharynx, and fibrosarcoma of the postnasal fossa are relatively rare, and found mainly in adults, but their chief symptom may be only a worrying persistent cough, analogous to the much commoner state of costermonger’s, stockbroker’s, or clergyman’s ‘sore throat’, which is due to a state of chronic pharyngo-laryngitis produced by repeated over-use of the voice—a state of affairs suggested by the patient’s occupation, the condition of granular pharyngitis seen, the absence of any evidence of worse trouble, and by the improvement that results from non-use of the voice.

3. Inquire whether any ordinary irritant, such as tobacco smoke, etc., brings it on; this, of course, at once raises the suspicion that the nasopharynx or larynx is unduly sensitive, and should lead to a careful examination of the region, whereupon a cause may be detected at once, such as chronic inflammation of any sort, or a long pendulous uvula, somewhat œdematous, or showing other signs of inflammation. Conditions of undue irritability without anything to see may remain for months after influenza or whooping-cough has passed away; such a cough is often complained of when convalescents go into a cold bedroom, or get into cold sheets at night.

4. Ask the patient to cough voluntarily; the curious barking or rough cough of laryngitis or of pressure on the trachea from aneurysm or growth, also the very striking cough of paralysis of the vocal cords, at once betray themselves.

5. Examine the chest carefully for heart disease or early phthisis; the cough of both these conditions is commonly dry; so too is the cough of the early hours of an oncoming bronchitis or pneumonia, but these can scarcely fail to give other indications. Children often suffer from very troublesome dry cough, sometimes persisting for months, as the result of reflex irritation from caseous or inflamed bronchial glands; the latter may be impossible of diagnosis from physical signs, but they can often be seen with the X rays (Fig. 155). Any mediastinal mass that irritates either the phrenic or the vagus nerve may produce most troublesome and persistent cough—big heart, mediastinal sarcoma or lymphosarcoma, aortic aneurysm; the cough is, as it were, nature’s effort to get rid of the irritating mass; and the diagnosis is sometimes quite obscure until the chest has been X-rayed.

6. Intestinal worms may be a cause of incessant and persisting cough, particularly in children, though adults are sometimes affected by the same cause. It would seem that, especially in the case of *Ascaris lumbricoides*, the ova derived from the adult worms in the bowel or swallowed in food infected from other individuals, hatch into embryos which pass into the blood-stream and have their habitat for a time in the lung tissues, causing persistent cough and even hæmoptysis, the cause for which may not be thought of at the time.

7. If no cause reveals itself by now, the stomach must be thought of, and its functional and physical conditions inquired into and examined ; not merely the stomach itself, moreover, but also many of the abdominal organs from which infection may spread to the under surface of the diaphragm—perihepatitis, perisplenitis, cholecystitis, gall-stones, tropical liver, coli bacilluria with perinephritis, gastric ulcer, duodenal ulcer, appendicitis ; only after negative results from all these inquiries and procedures may we think of a simple hysterical cough, though there are individuals who suffer daily from recurrent bouts of coughing, in whom no cause for these can be found and no further development or ill health ensues, and in whom, therefore, one becomes impelled ultimately to diagnose that their coughing bouts are little more than a bad habit or a sheer neurosis.

Cough with Expectoration. Expectoration generally makes the task of diagnosis much easier ; the very sticky sputum of any acute inflammation in its early stages, the rusty sputum of pneumonia, the stink of abscess or gangrene of the lung or of bronchiectasis, the nummulation of phthisical sputa, the frothy sputum of bronchitis, are often unmistakable. Small blood-clots or streaks make us apprehensive of early—but well-marked phthisis, or of mitral stenosis ; profuse hæmoptysis almost diagnoses acute phthisis in the absence of signs of an aneurysm or growth. Pus is a factor common to all inflammation of mucous membranes, and therefore in itself is of but little diagnostic value, though its quantity, colour, and odour may be suggestive of a phthisical cavity or of an hepatic abscess ruptured into the lung, of gangrene or stinking empyema. With hepatic abscess the sputum sometimes has an almost pathognomonic anchovy-sauce appearance.

In any case of cough with sputum the latter should be examined microscopically for tubercle bacilli ; discovery of the latter clinches the diagnosis. Their absence does not exclude phthisis, and the examination may need to be repeated several or many times before reliance can be put upon negative returns. It is generally wise to have the sputum tested for elastic fibres too, for these when present point to some grave lesion with actual destruction of pulmonary tissues. It is often advisable to investigate the general bacterial flora of the sputum by culture also, even in phthisical cases, to determine the nature of secondary infecting germs—*Streptococcus pyogenes*, *Staphylococcus aureus* or *citreus*, *pneumococcus*, Friedländer's *pneumobacillus*, or even diphtheria bacilli, influenza bacilli, or the organisms of Vincent's angina ; in quite rare cases aspergillosis or actinomycosis may thus be discovered in the course of routine investigation.

In no case in which there remains a doubt should X-ray examination of the thorax be omitted when skiagraphy is obtainable. X rays do not replace physical examination, but they are of very great value in checking one's opinion about chest cases.

The Age of the Patient. In babies and quite young children most of the more unusual causes of cough can be excluded at once on the mere fact of age, but the presence of a foreign body in the larynx is one of the unusual ones to be remembered, especially if the cough has come on suddenly in the midst of health. Bronchitis, bronchopneumonia, tubercle, pneumonia, whooping-cough, and diphtheria are far and away the most common causes in these young subjects, and owing to the absence of expectoration they do not reveal their presence without careful examination of the chest and throat. From infancy to middle life, the age of the patient gives but little assistance in determining the diagnosis ; but about middle age chronic bronchial troubles, quiet pleurisies, growths, aneurysms, become increasingly obtrusive, giving rise to a persistent cough, and only careful routine examination of the chest will reveal their presence.

How long have you had the cough ? Much information may be derived from the answer to this question, for a cough that has only lasted a few days, but in that time has become sufficiently severe to cause the patient to seek advice, is practically certain to belong to

Fig. 155.—Skiagram showing a large caseous bronchial gland in a child, causing cough persisting for months without expectoration, and difficult to relieve by medicine. H, Heart ; S, Gas in stomach ; C.G., Caseous gland.

the group caused by acute trouble, detectable when the chest is examined carefully, whereas, on the contrary, a cough that has lasted some months, and yet seems to the patient uncertain in its causation, is very likely to be due to some of the obscurer conditions—pressure of aneurysm, new growth, or glands, etc.—which need care to discover. The X rays are valuable in detecting thoracic aneurysms and new growths, and they are also of service in demonstrating phthisical and other lesions in many cases. Skiagraphic evidence is sometimes misleading, however, and the plates may be misinterpreted unless the shadows shown in them are taken into account, not by themselves alone, but always in conjunction with the other clinical data and physical signs. The so-called ‘root-shadows’ and the ‘radial striations from the roots’ are so common in healthy people, and so variable in their degree in different individuals, that much caution is needed before interpreting them as evidence of existent disease. Mediastinal masses may necessitate a picture being taken in the semilateral oblique position of the patient before they can be seen.

When does the cough come on? A cough in the morning only is suggestive of bronchial catarrh with accumulation of secretion during sleep. A cough on getting into bed suggests laryngeal irritability or a long pendulous uvula; but one that wakes the patient after he has gone to sleep makes one apprehensive of phthisis in the absence of other indications of obvious acute chest changes. A cough on exertion suggests heart trouble, and in determining the presence of this, the finest discrimination is required in auscultation, for these are typically the cases of morbus cordis without a bruit in which frequency of rhythm and good differentiation of the first and second sounds are all-important for a diagnosis. Shortness of breath will generally be a marked symptom associated with the cough in these cases (see BREATH, SHORTNESS OF, p. 113).

Has the voice altered since the cough appeared? Laryngeal inflammation, tuberculosis of the larynx, syphilis of the larynx, epithelioma of the larynx, paralysis of a vocal cord, or compression of the trachea by a large goitre or by an aneurysm or mediastinal new growth are suggested by an affirmative answer, and the larynx must be examined carefully, the more carefully the more nearly the patient is approaching to the period of life when growths are more common.

Cough and Vomiting.—These two complaints are not infrequently made together by patients, and there is a very useful but often forgotten question to put, viz., “Are you sick independently of the cough? or do you cough till you are sick?” Yes to the first suggests stomach trouble; yes to the second suggests whooping-cough, chronic bronchitis, fibroid lung with bronchiectasis, empyema ruptured through a bronchus, hepatic abscess ruptured into a lung, phthisis with large cavities, mediastinal masses such as huge heart, new growth, or aneurysm, or subdiaphragmatic irritation such as a subphrenic abscess might cause.

Herbert French.

CRACKLING, EGG-SHELL.—This is a condition closely allied to CREPITUS (p. 190); if subcutaneous emphysema, arthritis, and tenosynovitis can be excluded, it is nearly always a symptom either of osteosarcoma, if it occurs in connection with a long bone, or hydrocephalus or craniotabes in the case of the occipital or other cranial bones. The X rays may assist the diagnosis; if there is a tumour connected with the end of a long bone which exhibits egg-shell crackling with or without pulsation, it is almost certainly an osteosarcoma or a myeloid sarcoma.

Herbert French.

CRAMPS are involuntary tetanic muscular contractions accompanied by sharp pain in the voluntary muscles involved. Temporary paralysis of movement, partial or complete, is often associated with cramp. Similar painful spasms of the involuntary muscles are referred to as COLIC (p. 147). In most instances, cramps result from *over-exertion* of the affected muscles. The cramp comes on at once, or after a short delay, or when the attempt is next made to use the muscles involved. The most striking example of this is *swimmer's cramp*; in this the victim is overtaken suddenly by painful spasm and paralysis of the muscles of the leg or legs, or of the legs or arms; he is likely to drown unless help is speedily forthcoming. Similar but less extensive cramps are not rarely experienced by persons taking part in the more violent of outdoor games—football, hockey, lacrosse, etc.; some particularly sudden or violent effort may be followed by cramp in the thigh- or calf-muscles. Similar cramps of the legs are familiar to rowing men and ballet-dancers.

Certain people have a great proclivity to cramp during the night, and it seems to return with less and less provocation the more often it is experienced. Stokers and iron-founders who do heavy bodily work in a much overheated atmosphere are liable to heat cramps, severely painful spasms in the muscles of the limbs and abdomen, in attacks lasting for many hours and followed by great weakness. The diagnosis of cramps due to over-exertion, directly associated as they are with a definite history of muscular strain, should not be difficult. They rarely become so severe as to prevent their victims from continuing to take part in the occupations that provoke their occurrence.

It is quite otherwise, however, with patients who are afflicted with the so-called *professional cramps* or *occupation neuroses* that result from chronic strain and over-use of certain groups of muscles. They occur in such persons as writers, typists, telegraph operators, compositors, painters, tailors, seamstresses, dairymaids (from milking cows), pianists, flute-players, violinists, 'cellists, drummers, blacksmiths, file-makers, cigarette-rollers, and so forth. In all these employments, particular groups of muscles are in constant and special employment. If they are overworked they may become the seat of cramps and aching pains—professional cramps—as soon as they are used: their movements lose their delicacy, and become inco-ordinated and spasmodic. A fine tremor is very commonly to be observed in the affected limb. It is probable that over-use alone is not enough to set up these cramps. Anxiety, ill-health, local injury or disease, and the inheritance of a neurotic temperament, all contribute to the establishment of professional cramps. These cramps have also been recorded in other occupations, and as affecting other groups of muscles: in treadler's cramp, the hamstring muscles and glutei are affected: in cornet player's the tongue, in watchmaker's the orbicularis oculi, may be attacked. As a rule, the diagnosis of a professional cramp is not hard, but it is necessary to make sure that neither organic nervous disorder nor local disease is present. Thus the physical signs, though hardly the symptoms, of writer's cramp may be present in such diseases as paralysis agitans, disseminated sclerosis, tabes, general paralysis: brachial neuralgia might simulate the neuralgic forms of occupation neurosis, but it is free from cramps. Again, affections of the joints or of the tendons at the wrists, such as chronic rheumatism, rheumatoid arthritis, tenosynovitis, tuberculous infection, may all give rise to pain in, and interfere with, the movements of the hand. Again, writer's cramp may be so much feared by nervous patients that the right hand may become so stiff, or weak, or painful, that they can no longer write: objective signs of the cramp, however, are lacking in such cases, which are cured by the re-establishment of the patient's self-confidence.

Cramps are the main feature of *tetany*, a disease characterized by the occurrence of paroxysmal or continued tetanic spasms of the extremities, and increased excitability of the nerves and muscles to electrical or mechanical stimulation. Tetany occurs in many different conditions, and at any age. In infants and young children it is a complication of rickets, improper feeding, and acute gastro-intestinal disorders, either with or without diarrhoea and vomiting. Epidemics of tetany in young adults, probably resulting from food-poisoning, have been described on the Continent, though not, apparently, in Great Britain. In nursing women tetany may follow prolonged lactation, or it may develop during pregnancy and recur in successive pregnancies. It may result from the removal of too much or all of the thyroid gland in either sex. Tetany complicates a certain proportion of the cases of gastrectasis, occurring whether the dilated stomach has been washed out or not. A few instances are on record in which tetany followed the acute specific fevers, enteric fever, or poisoning by chloroform, lead, or ergot. The cramps of tetany are mainly in the extremities, and paroxysmal: they may continue, however, for hours or days, and are very painful. During the spasms, the fingers are extended at the terminal and flexed at the metacarpophalangeal joints and pressed together, while the thumb is adducted and flexed into the palm, so that the so-called 'accoucheur's hand' (*Fig. 1*, p. 2) is produced. The wrist and elbow are flexed, the arms being usually folded over the chest: exceptionally the elbow may be extended stiffly. The toes are drawn together and flexed, the foot is arched and turned inwards, and the ankles and knees are extended. Usually the limbs only are involved, but in severe cases cramps occur in the face, neck, and even the trunk, when respiration may be embarrassed seriously. The rigid muscles are very tender to the touch. Three special signs are present in the intervals between the attacks of tetany, and are valuable in diagnosis: these are Trousseau's sign, or reproduction of the

paroxysm by manual compression of the nerves or blood-vessels supplying the affected parts: Erb's sign, or hyper-excitability of the motor nerves to electrical currents (0.5 to 2.0 milliampères); and Chvostek's sign, or reproduction of the spasm in the facial muscles by tapping either on the muscles themselves or on the facial nerve. Tetany must be diagnosed from *tetanus*, in which the spasms begin in the head and neck, and trismus is an early symptom; and from *strychnine poisoning*, where the spasms are clonic rather than tetanic, and affect the whole body, and not the extremities primarily or principally. In the *carpo-pedal spasms* of rickety children or of infants with severe gastro-intestinal catarrh, the cramps are similar to those of tetany, but are transient, and perhaps affect the hands only, or the hands and arms. Such spasms may justly be regarded as identical with mild tetany. *Hysterical tetany* occurs, and is to be distinguished from true tetany by its association with other hysterical stigmata on the one hand, and on the other by the absence of Trousseau's and Chvostek's signs. Hysterical tetany may also, perhaps, be distinguished by its failure to respond to the exhibition of calcium salts; the most recent view of true tetany regards it as the expression of hyper-excitability of the nerve-cells due to lack of calcium salts, and connects it with the parathyroid glands by supposing that they control the calcium metabolism of the body.

Reference may again be made to the fact that cramps are prone to occur in patients debilitated by the *acute fevers* or *enteric fever*; severe cramps in the legs and arms are often a highly troublesome feature of the convalescence from *cholera*. In many chronic diseases nocturnal cramps may give rise to no little distress, or may interfere seriously with sleep; in *gout*, *chronic Bright's disease*, *uræmia*, *alcoholic neuritis*, and almost any chronic wasting disorder, complaint of cramp is not infrequent, but in such instances more serious signs or symptoms of disease will be evident.

A. J. Jer-Blake.

CREPITUS is a term generally used to denote the grating or crackling sensation and noise produced when two ends of a broken bone grate together. It is the most conclusive

sign of a *fracture*; but it causes the patient so much pain that whenever the X rays can be employed attempts to obtain crepitus should not be made with any vigour. Apart from fracture of a bone, crepitus is also to be felt and heard in joints affected by dendritic synovitis, or still more so in cases of *osteo-arthritis*; the term 'silken crepitus' has been used for the sensation felt on moving such a joint, comparable to the rubbing together between the fingers of two pieces of stout silken ribbon. *Tenosynovitis*, especially around the flexor tendons at the wrist, may also produce a marked feeling of crepitus, especially in cases where the tendon-sheaths contain melon-seed bodies.

When there is an enlargement of a bone without fracture, and when on palpation a feeling of crepitus or egg-shell crackling is obtained, it is an indication that the tumour is a deposit of secondary carcinoma or a primary rarefying *osteosarcoma* or *myeloid sarcoma*, which may sometimes be felt to pulsate also. The diagnosis may be assisted by the use of the X rays (*Fig. 156*).

Rarefaction of the bones of the skull, either as the result of syphilitic lesions in adults, or of *hydrocephalus* or *craniotabes*, especially in the occipital region of congenital syphilitic and rickety infants, may make the skull bones

so thin that they readily bend on pressure, and sometimes the result is a sensation of crepitus. The diagnosis is generally obvious.

Quite apart from bony, arthritic, or synovial changes, a characteristic feeling of crepitus may be felt beneath the skin when gas or air has accumulated in the subcutaneous tissues as the result of surgical EMPHYSEMA (p. 254).

Herbert French.

CRUSTS ON THE SKIN.—(See SCABS, p. 742.)

CUD-CHEWING.—(See MERYCISM, p. 485.)

CURSCHMANN'S SPIRALS consist of a highly refractile central fibre with a sinuous wavy sheath of mucus. They may be half an inch in length, but they are very slender. They occur in the sputum of patients suffering from true spasmodic asthma, and they may be associated with eosinophil corpuscles and Charcot-Leyden crystals. They are pretty objects, best seen in fresh sputum, but their diagnostic significance is very limited, first because they are so often absent in cases of undoubted asthma, and secondly because they have been found in bronchiolitis without asthma. They seem to be casts of the finest bronchioles. It is probable that, if there were doubt as to whether a given case were one of primary emphysema and bronchitis, or of spasmodic asthma that had led to emphysema and bronchitis, the occurrence of typical Curschmann's spirals would point to the latter. There are, however, other means of arriving at the same conclusion, particularly the history, the age at which the first attack began, and the presence or absence of EOSINOPHILIA (p. 271).

Herbert French.

CURVATURE, SPINAL. The first thing is to distinguish between lateral and antero-posterior deformities. Lateral curvature (scoliosis) of the spine is generally postural, seldom the result of tuberculosis or other serious organic bone disease; whereas antero-posterior deformity forwards (kyphosis) is suggestive of tuberculous, cancerous, or inflammatory bone disease, and similar deformity backwards (lordosis) suggests either nerve disease or congenital dislocation of the hips. This generalization is of considerable importance, for by no means every lateral curvature of the spine merits the drastic treatment by long rest in the supine posture sometimes ordered, though it is true that in a certain number of cases scoliosis or lateral curvature is complicated by antero-posterior deformity, kyphosis or lordosis, as well, and in a few instances of angular kyphosis due to caries there is some lateral deviation which is generally much more abrupt than is the curve of scoliosis. A good way of demonstrating lateral curvature is to pencil the skin over the spinal processes.

LATERAL CURVATURE—SCOLIOSIS.

The following are the most important causes of lateral curvature:—

Inequality in the lengths of the lower limbs	Paralysis of the muscles of the back, as in infantile paralysis, peripheral neuritis, especially that following diphtheria, and some of the muscular dystrophies
Weakness of the muscles of the back associated with bad habits of standing or sitting	Shrivelling of one side of the chest as the result of emphysema or fibroid lung
Carrying heavy weights with one arm or on one shoulder	Hysteria.
Rickets	
Wry-neck, or other cause of asymmetry of head and shoulders, e.g., Sprengel's shoulder	

Inequality of the lengths of the lower limbs is one of the commonest causes of lateral curvature; therefore it is very important to find out at once if the legs are equal. The most reliable and easy method of determining this is to get the patient to stand up with both knees straight and without resting a hand upon anything. The observer then stoops in front of the patient and places his thumbs, with their extremities upwards, exactly upon the prominence of each anterior superior spine. The eye can then detect even a slight difference in the level of the two spines. This method is far more reliable than measurement from the anterior superior spines to the malleoli. Moreover, the latter method does not show shortening due to flexion and adduction of the hip-joint. Further, the foot may be fixed in a position of talipes equinus, which may make a short limb apparently longer than its fellow, so that the anterior spine on the corresponding side may be elevated. When the anterior spines are on a different level the trunk leans towards the lower spine, but in order to maintain the erect position the upper part of the body becomes flexed to the opposite side: the spine in the lumbar region consequently developing in a curve with its convexity to the side of the short limb. Lateral curvature due to a shortened limb, in its early stages, is corrected at once by compensating the shortened limb, and it also disappears when the patient sits on a flat level surface.

In the absence of inequality of the limbs, *muscular weakness* is by far the most common

cause of lateral curvature. The spine does not become straight when the patient sits on a flat level surface; but in the early stages of the deformity the shape can be corrected somewhat by muscular effort.

Asymmetry of the chest following upon empyema or fibroid lung is detected easily by ordinary physical examination of the thorax. The shrivelled side is generally less resonant on percussion, and there are other signs of pulmonary disease.

Scoliosis secondary to *wry-neck* is usually slight, and limited to the cervical and dorsal regions.

In growing youths the *carrying of heavy weights* with one arm or upon one shoulder is a common and important cause of scoliosis, and it is therefore necessary to go into the question of occupation and habits. For instance, nursery-maids and butchers' boys are apt to develop lateral curvature as the result of carrying burdens upon the right arm.

The lateral curvature due to *rickets* is recognized by the unusually early onset, during the first or second year, and the signs of rickets in other parts, especially thickening of the lower end of the radius. The direction of the primary curve is sometimes explained by the pressure of the arm of the nurse who carries the baby too exclusively on one arm.

Fig. 157. Sialogram of secondary carcinoma affecting the 1st lumbar vertebra. The new growth is indicated by an arrow. (Fig. Dr. W. H. Coburn.)

Actual *paralysis of the spinal muscles* is a rare cause of scoliosis, and is to be recognized by the wasting of the spinal muscles, especially when it is more marked on one side.

The sinking of the muscles due to atrophy of the spine must not be mistaken for wasting. There is usually paralysis of other muscles, especially those of the leg. Scoliosis is often seen in the various primary muscular atrophies (p. 624), and in Friedreich's hereditary ataxy (p. 624).

Peripheral neuritis as a cause is nearly always due to diphtheria or sore throat. The history may indicate

this, or there may have been other post-diphtheritic paralyses, notably that of the soft palate, with nasal voice and regurgitation of fluid through the nose. Cultivations should be taken from the throat, and the Klebs-Löffler bacillus (Fig. 608, p. 779) may be found if sought early enough. Occasionally the abdominal muscles may also be paralysed in these cases, and this is a contributory cause of the curvature.

Fig. 158. Sialogram from a case of former carcinoma of the breast from which secondary deposits developed in the spine, producing severe pain in the back and along the intercostal nerve. The sialogram was taken in the lateral position, and it shows pronounced collapse of the 11th lumbar vertebra; it shows also similar but less marked collapse of the 11th dorsal vertebra. (Fig. Dr. C. Thurston Holland.)

ANTERO-POSTERIOR CURVATURES.

These may take the form of: (1) *Kyphosis*; (2) *Lordosis*.

1. **Kyphosis** or '**Hump-back**.'— This means a bending forward of the upper part of the back on the lower. The curve may be (a) *Angular*, limited to a small portion of the back; or (b) *Diffuse*, or even general, extending from the coccyx to the cranium.

a. **ANGULAR KYPHOSIS.**

The causes of angular kyphoses are: (i) Tuberculous caries of the vertebrae; (ii) Growth of the spine; (iii) Hydatid disease of the vertebrae.

i. *Caries* is by far the commonest cause, and it is very important to recognize the disease before the deformity becomes well marked. Unfortunately it may be treated for a long time as stomach-ache or intercostal neuralgia, because the pain is referred to the abdomen and the intercostal regions. During its active stages it is easy to recognize it from its classical symptoms and signs. The patient avoids all jerky

Fig. 159. Osteitis deformans in a man. Fig. 160. Osteitis deformans in a woman.

Fig. 161. Skiagram of tibia and fibula in a case of osteitis deformans. The tibia is bent and thickened, in contrast to the normal fibula. (By Dr. F. Talbot Nodding.)

movements, walks with a stooping gait, and grasps with the hands any convenient article of furniture. The spine is tender on percussion, also on pressure upon the head or shoulders. Local rigidity of the back is noticed when the patient attempts to stoop. In later cases paralysis of the legs may complicate the deformity. In the quiescent stages the diagnosis is based on the characteristic local deformity and rigidity. Skiagrams, especially those taken from side to side, may afford material help by showing evidence of destruction of the bodies of the vertebrae (Fig. 451, p. 565). In some cases, lateral curvature as well as kyphosis may complicate or follow caries, and then the diagnosis is not easy. The disease may have affected the bodies of the vertebrae unevenly, leading to some lateral deviation, which is usually rather abrupt and associated with the local rigidity characteristic of caries.

ii. *Growth of the spine* is a rarer cause of angular curvature. Rapidly developed curvature in a patient after middle age may be due to secondary carcinoma in the bodies of the vertebrae, and bearing this possible cause in mind the surgeon should go carefully into the history, and examine every possible source of primary carcinoma, particularly the breast (Figs. 157, 158). Primary or secondary sarcoma may also

lead to deformity of the spine, and in some cases X-ray examination may give evidence of the absorption of the vertebrae.

iii. *Hydatid disease* is a rare cause of spinal curvature, and it is usually not limited to the spine. The diagnosis may be impossible unless there is collateral

evidence of hydatid disease elsewhere in the patient; the condition would most likely be mistaken for tuberculous caries or for new growth. X-ray examination of the spine is not distinctive.

b. **DIFFUSE KYPHOSIS.** The back may be bent forwards in a uniform curve extending from the coccyx to the cranium. This variety is common in *rickets*, owing to the premature assumption of the sitting position when the bones are soft and the muscles of the back are weak. When the patient is lying prone the deformity can be corrected by raising the legs. Moreover, there are other signs of rickets, such as enlargement of the lower end of the radius, beading of the ribs, and delay in the eruption of teeth. A similar deformity arises from *muscular weakness* due to other causes, such as idiocy, congenital spastic paraplegia, primary

Fig. 162.—Dea-porter's bursa over vertebra prominens.

Fig. 163.—Myopathic lordosis.

muscular dystrophy. In all of these there is an entire absence of rigidity of the spine.

An extensive and uniform curve, affecting the cervico-dorsal region, is common during adolescence, and is due to muscular weakness, lazy habits, and the carrying of heavy weights. In its early stages the deformity is easily reducible, and as a rule is compensated by a marked lordosis in the lumbar region, and some tilting backwards of the occiput. It is often associated with lateral curvature, and in some cases may be partly due to shortness of sight. The condition is distinguished from caries by the diffuseness of the curvature, the absence of pain and local tenderness, and the comparative suppleness of the back.

Kyphosis due to *spondylitis deformans* or to *osteitis deformans* (Figs. 159 and 160) is of a more uniform character without complicating lordosis, and the deformity is irreducible. There is generally evidence of the disease in other parts, such as osteo-arthritis, or the bending of the legs, thickening of the tibiae or other long bone, and increase of the size of the head, which are due to *osteitis deformans* (Fig. 161). Porters carrying heavy weights on the upper part of the back prematurely develop the kyphosis which is usually associated with old age. They frequently have a bursa over the seventh dorsal spinous process (Fig. 162).

Fig. 164.—A case of congenital dislocation of the hips, showing the stance and pronounced lordosis. (Photographs kindly supplied by Dr. Haworth, of Carshalton.)

2. **Lordosis, or Hollow-back.**—This is common only in the lumbar and lower dorsal regions. The natural hollow of the loin is exaggerated, and usually there is either primary or compensatory kyphosis in the

cervico-dorsal region (*Figs. 163 and 164*). Lordosis is rarely primary, but it may be so in the early stage of lumbar or lumbo-dorsal *caries* in children, when the real cause of the deformity is apt to be overlooked. The abdomen is prominent, and the back is not only hollow, but rigid and tender. Pressure upon the head causes pain in the back. In some cases the deformity is exaggerated by induration or suppuration in the psoas muscle which complicates this disease. Lordosis is not uncommonly due to *weakness or paralysis of the muscles of the back* (*Fig. 163*). It is important to look for other evidence of primary muscular dystrophy. The upper part of the back is then thrown backwards to facilitate the maintenance of the erect position. Lordosis is often secondary to the flexion of *hip disease*, which must not be overlooked. Limitation of movement especially of rotation of the hip-joint and wasting of the thigh, serve to demonstrate the existence of this disease. Lordosis and the waddling gait may be the first indications of *congenital dislocation of the hip* (*Fig. 164*). In this condition, one almost confined to the female sex, the erect position is maintained only by throwing the shoulders backwards to an unusual

Fig. 165. Skiagram showing the deficiency of the head of the femora and of the acetabular cavities in a case of so-called congenital dislocation of the hips. (*Fig. 165*, W. H. Caldwell.)

degree in order to bring the trunk in a line with the heads of the femora, which are dislocated backwards. The suspicion of congenital dislocation of the hip may be confirmed by skiagraphy (*Fig. 165*), by the gliding movements of the head of the femur upon the pelvis, the unnatural width of the hips, the hollow appearance of Scarpa's triangle, and by palpation of the head of the femur upon the dorsum ilii when the thigh is flexed, strongly adducted, and inverted. *Contortionists* usually have a good deal of lordosis owing to the unnatural suppleness of the lumbar spine and the elongation of the hamstrings. In all these conditions the back is supple, and can be restored to its natural shape by placing the patient in the supine position and flexing the thighs.

R. P. Rowlands.

CYANOSIS, EXTREME. Extreme cyanosis, blueness, or lividity is generally most marked in the face; next in the extremities, especially the hands, feet, ears, and penis; and least in the trunk. Cases in which it is a prominent symptom may be divided into two main groups, according as the cyanosis is present at or soon after birth, or occurs

later in the life of a patient originally free from it. Congenital cyanosis of extreme degree is nearly always due to *malformation of the heart*, particularly *pulmonary stenosis* (Fig. 166). *Patent septum ventriculorum* may also produce the symptom, though not in so marked a degree, whilst *patent ductus arteriosus*, when it occurs by itself, is generally not associated with cyanosis at all. These three conditions all give rise to loud universal bruits, of which that due to pulmonary stenosis is purely systolic, with its maximum intensity in the second left intercostal space close to the sternum; that due to patent septum ventriculorum is also systolic, but has its maximum intensity lower down the sternum, usually between the two third spaces or fourth ribs; whilst the bruit of patent ductus arteriosus is not purely systolic, but continues through both systole and diastole, with its maximum intensity at the time of the second sound, and it is best heard in the third left intercostal space, about half an inch out from the sternum; all these bruits may or may not be accompanied by a corresponding thrill, the latter generally being least marked with patent septum ventriculorum. Extreme CLUBBING OF THE FINGERS and of the toes accompanies the cyanosis in most cases (Fig. 126, p. 143). In addition to these three types of congenital heart disease there are other cases in which extreme cyanosis, with or without clubbing of the fingers, occurs without any definite bruits, and the diagnosis of the nature of the lesion can only be guessed at. There may or may not be transposition of the great

vessels or of the viscera at the same time. Sometimes there is a single large vessel, the pulmonary artery coming off from the aorta; or there may be only one ventricle, or a single auricle. It is almost impossible to decide between the various possible lesions unless there is one of the definite bruits just described. Anomalous cases seldom survive, but some cases of pulmonary stenosis or patent septum ventriculorum reach adult life, and patent ductus arteriosus often gives little inconvenience to the patient at all. It is to be remembered that patent foramen ovale is quite undiagnosable, that it causes no symptoms, and is present in a large percentage of normal people.

Cyanosis developing in children or adults who have hitherto been healthy is generally due either to laryngeal or tracheal obstruction, to lung lesions, cardiac failure, obstruction to the superior vena cava, or to some alteration of the blood itself, such as is found in splenomegalic polycythæmia, methæmoglobinæmia, sulphæmoglobinæmia, or the later stages of diseases associ-

Fig. 166. Morbus cordis; congenital pulmonary stenosis with extreme cyanosis.

ated with extreme loss of fluid from the tissues, especially cholera maligna. The differential diagnosis is usually easy up to a certain point: not a little cyanosis may result from taking certain *drugs* either in large quantities at a time, or in less quantities continually—veronal, trional, sulphonal, phenazone, phenacetin, and acetanilide in particular (Fig. 167). The urine in these cases often reduces Fehling's solution, and may contain methæmoglobin, recognizable by the spectroscope. The diagnosis depends on a knowledge of the drug that is being taken. Cases of *pancreatitis* often exhibit a peculiar cyanotic hue. The fact of *laryngeal obstruction* is generally obvious from the stridor, and from the way in which the larynx moves forcibly up and down with respiration. The cause of the obstruction may be less easy to determine. In a child, a digital examination of the back of the mouth should not be omitted, lest there be a *post-pharyngeal abscess* or a *foreign body*; in the absence of this, the most probable cause is *diphtheria*; though it may be difficult to diagnose forthwith between *laryngitis with intermittent spasm*, *laryngismus stridulus*, *acute obstructive laryngitis*, and *diphtheria*. Swabbings should be taken from the throat as far back as possible, and examined bacteriologically. The bacillus of diphtheria (Fig. 608, p. 779) may be found on direct examination of films stained by Neisser's method; but sometimes they cannot be found until cultivations have been made, and this takes upwards of twenty-four hours. If there has been no obvious cause for catarrhal laryngitis, such as the inhalation of irritant gases or a recent attack of acute bronchitis affecting the large tubes, it is better

to assume that the condition is diphtheria until it is proved not to be so. The occurrence of other cases in the same house, or in the neighbourhood, may assist the diagnosis.

Another condition which may simulate diphtheria from the extreme dyspnoea and cyanosis that result is the *inhalation of a foreign body*, such as a button, small shell, piece of food, a tooth, and so on : or obstruction to the trachea by a bulging *caseous gland* (Fig. 168). In an older person, *acute suffocative laryngitis* due to pneumococci or streptococci is associated with extreme cyanosis of rapid onset. Tracheotomy is necessary, and the diagnosis is arrived at upon bacteriological grounds. When similar acute infective changes occur, not in the larynx only but in the root of the tongue as well, thence infiltrating the deep structures of the neck, as in *angina Ludovici*, cyanosis and dyspnoea may be very marked : the diagnosis is suggested by the acute brawny swelling of the neck and by the changes in the floor of the mouth and tongue. Severe dyspnoea and cyanosis may accompany *goitres*, whether simple, exophthalmic, or malignant : the attacks

Fig. 167. Cyanosis of the face, the result of taking antikamnia.

Fig. 168. Bronchoscopic appearance of a case of tracheal compression from enlarged glands. There was extreme dyspnoea and cyanosis in this case, relieved at once by the passage of the bronchoscope.

may be paroxysmal even though the thyroid gland itself does not seem to vary in size : or the cyanosis and dyspnoea may be continuous when there has been rapid enlargement of the gland from rarities such as hemorrhage into it, acute suppuration in it, or from progressive and extreme fibrosis of the organ such as is seen in *ligneous thyroiditis*, or Riedel's disease (see THYROID GLAND, ENLARGEMENT OF, p. 876). It is difficult to inspect the vocal cords in a child : but in an adult this is easier, and direct examination serves to distinguish between acute or ulcerative lesions of the larynx and laryngeal paralysis : the latter, sometimes the result of syphilitic degeneration of part of the vagal centre in the medulla, is apt to produce *bilateral abductor paralysis* with adductor spasm, which may come on acutely and simulate acute asphyxia

from a foreign body. *Tuberculous, syphilitic or malignant, variolous, leprous, lupoid, and traumatic ulceration* of the larynx, may any of them become acutely infected by

inflammatory organisms, and lead to comparatively sudden and severe laryngeal stenosis with acute cyanosis: the diagnosis will depend upon the history, bacteriological examination, and direct examination of the vocal cords. *Bright's disease* has sometimes caused similar symptoms, due to acute œdema of the larynx, and *potassium iodide* may do the same in those who are particularly prone to iodism. Knee-jerks should be tested, and the pupils examined, lest acute attacks of dyspœna with cyanosis simulating laryngeal obstruction are due to the laryngeal crises of *tubercularis*.

Growths of the lung, particularly if they give rise to pleuritic effusion or to obstruction of a bronchus, may cause progressive cyanosis: the diagnosis is not as a rule easy in the earlier stages, but if there is evidence of progressive interference with the structures within the thorax, with ultimate stenosis of the superior vena cava, and the results of this, namely, œdema of the face and arms, together with cyanosis of these parts out of proportion to any similar change in the legs, the diagnosis lies between growth, aneurysm, and mediastinal fibrosis. The X rays will sometimes be of material assistance in deciding. A rare but very alarming complication of thoracic aneurysm is for the latter to open suddenly into the superior vena cava: the result is acute dyspœna, extreme cyanosis of the face and hands, and bloated-looking swelling of the head, face, neck, arms, and upper part of the chest and back (*Fig. 169*). The diagnosis is suggested at once by the suddenness

Fig. 169.—Extreme cyanosis from the bursting of an aortic aneurysm into the superior vena cava. The patient was of normal appearance until, almost suddenly, his face and neck increased enormously in size and became violaceous without being definitely œdematous; and at the same time a roaring systolic bruit developed in the first and second right intercostal spaces near the sternum, where there had been no bruit previously. There had been a brassy cough for some time. The patient survived the acute obstruction to his superior vena cava a few months. The photograph, taken when he was lying ill in bed, shows the bloated appearance that resulted.

the onset of the graver symptoms; though these have also been produced in rare cases by such lesions as sudden *hæmorrhage into the mediastinum or thymus gland*, or similar *hæmorrhage into an intrathoracic sarcoma* or other new growth.

Phthisis, in the later stages, particularly when it advances rapidly and leads to generalized caseous bronchopneumonia, causes extreme cyanosis in some instances. The diagnosis will generally have been made long previously, from the symptoms, such as hæmoptysis, cough, and wasting; from the abnormal physical signs which started at the apices of the lungs and were progressive; and from the discovery of tubercle bacilli and elastic fibres in the sputum, though there are many cases of *miner's phthisis* (*Fig. 170*), or pneumoconiosis, in which the lung trouble may be extensive, yet tubercle bacilli cannot be found; there is doubt as to whether this condition is always tuberculous and not sometimes syphilitic.

Pneumothorax, when it comes on suddenly in a patient who has had no symptoms hitherto, leads to acute dyspœna and cyanosis, which presently pass off; the physical signs are pathognomonic, and the cause is generally tubercle.

Embolism of the lung, if the artery occluded is of large size, may cause sudden death, so that the patient hardly has time to become cyanosed; when the embolus blocks a

smaller vessel, lividity, dyspnoea, intrathoracic pain, and hæmoptysis are the most prominent symptoms; the diagnosis is suggested by the suddenness of the onset in a case in which there is a cause for embolism, particularly thrombosis of a vein such as the femoral or iliac, or a recent surgical operation in the neighbourhood of a large vein such as those in the abdomen, or otitis media with lateral sinus thrombosis, or a cardiac lesion such as infective endocarditis of the right side of the heart. There may be no abnormal physical signs; but sometimes the resultant infarct may be detected by the impairment of percussion note, the deficient vesicular murmur, and the development of a rub over it.

In childhood, the commonest lung affection to produce extreme cyanosis is *bronchopneumonia*; the diagnosis is generally obvious, though it is not always easy to determine whether, in a case in which there is some evidence of laryngitis at the same time, the cyanosis is due mainly to the laryngeal obstruction or to the intrapulmonary lesions. Each may cause extreme sucking in of the intercostal spaces and convulsive movements of the chest as a whole; but the best measure of the degree of laryngeal obstruction is the violence of the up-and-down movements of the larynx itself. There may or may not be *empyema* associated with bronchopneumonia; but the degree of cyanosis will not help to distinguish between these two; needling of the chest will be resorted to when there is ground for supposing that empyema may be present. Severe *bronchitis* and *emphysema* in middle age often lead to marked cyanosis and orthopnoea, owing no doubt to the failure of the right side of the heart to which the lung trouble gives rise. The over-distended condition of the chest, its small difference between maximum inspiratory and maximum expiratory girths, the deficiency of the vesicular murmur, the rhonchi all over it, and perhaps non-consonating râles at the bases, will indicate the diagnosis, particularly if the patient has inelasticity of the skin of the back of the hands, and has suffered from similar attacks for some years past, especially in the winter. The chief difficulty will be to determine whether the cause of the cyanosis is pulmonary or cardiac. *Lobar pneumonia* as a cause of acute cyanosis is diagnosed chiefly by a history of sudden onset, the continuance of pyrexia for a week or ten days and ending by crisis (*Fig. 617*, p. 789), the rapid respiration-rate in proportion to the temperature, the viscid rusty sputum, and herpes labialis. Occasionally the pyrexia terminates by lysis or in some other atypical way (*Fig. 171*) instead of by crisis; or it may rise again after the crisis, particularly when empyema follows (*Fig. 171*). Sometimes the diagnosis is made when no abnormal physical signs can be detected; but if over a large portion of a lobe there is at the same time impairment of note, with bronchial breathing, bronchophony, pectoriloquy, without râles at the height of the malady, but with fine crepitations at the beginning of the attack, and with redux crepitations as the bronchial breathing disappears after the crisis, the diagnosis

Fig. 170. Skiazgram of a case of miner's phtisis in a man, age 55, who had been a worker in the Rand gold mine. There was three years' history of lung trouble, though the man had won a mile race a year before. He was now a typical asthmatic with sputum, but without detectable tubercle bacilli. He died a few months after the skiazgram was taken. (*See Dr. C. Thorstein Hoffman.*)

will be obvious, especially if during the fever there is a great deficiency or complete absence of chlorides from the urine and there is rusty sputum.

Asthma is sometimes very difficult to distinguish from bronchitis and emphysema, because it ultimately gives rise to both the latter (p. 653). It may produce extreme cyanosis during an attack.

During the severe epidemic of 'influenza' in 1918-19, when so many patients died of the so-called 'influenzal pneumonia', cyanosis of extreme degree (Figs. 172-174) was a very marked phenomenon, and it was associated with extreme gravity of the prognosis whenever it occurred. Sporadic cases of a similar kind are met with still, but it is to be hoped that it will be many years before there is any recurrence of the trouble in epidemic form. The condition is seldom one of true pneumonia, or even of bronchopneumonia; but is rather one of acute exudative oedema of the lung tissues generally, followed by varying degrees of actual bronchopneumonia if the patient survives long enough to

Fig. 171. Termination of a case of lobar pneumonia by lysis followed by emphysema.

produce the latter. The exudative oedema is the main factor in preventing oxygen penetrating to the pulmonary capillaries, and the cyanosis results from anoxaemia, which is neither cardiac nor intrinsically pneumonic.

A similar state of affairs with extreme cyanosis is seen in cases of *pneumonic plague*; and during the war cyanosis as the result of acute *gas poisoning*, either by chlorine or by other gases such as phosgene, was common owing to the special circumstances of the times.

The cause of the cyanosis in these cases is exudative oedema of the interstitial and alveolar spaces of the lung, analogous to that found in influenza-pneumonic cases.

Extreme cyanosis may result sometimes from coming too rapidly to the surface from depths of the sea, as in *caisson disease* or in *divers* affected by some error in the aerating plant or in the rate of bringing to the surface; and occasionally there is seen extreme cyanosis after injuries involving crushes to the abdomen or chest, even when there is no objective evidence of injury to heart, lungs, or big vessels; in the case illustrated in Figs. 175, 176, the girl, age 11, had been knocked down by a motor omnibus and crushed by the protecting guard, which caused superficial bruising of the abdomen and chest but broke no bones, led to no hæmoptysis, did not cause any peculiarity in the action of the heart, and gave rise to neither dyspnoea nor orthopnoea; what is the precise cause of such extreme *traumatic cyanosis* is difficult to say with certainty; the patient made a good recovery in less than a month.

Cardiac causes for extreme cyanosis include any of the conditions which lead to *chronic failure of the right side of the heart*. These may be classed into one or other of four main

groups—namely: primary *valvular disease of the heart*; affection of the *muscle of the heart* or pericardium; failure of the heart as the result of *chronic lung lesions*, especially emphysema, bronchitis, fibroid lung, and bronchiectasis; and cardiac failure when the heart is unable to maintain the *high blood-pressure* due to granular kidney or arteriosclerosis. When a late stage in the failure of compensation has been reached, it is often difficult to determine whether the primary condition is kidney, heart, lungs, or arteries; the differential diagnosis between these is considered on page 17.

Fig. 172. The pre-cyanotic stage of acute influenza pneumonia, showing flushing, drooping eyelids, but no blueness.

Fig. 173. The pre-cyanotic stage of acute influenza pneumonia. The patient is cyanotic. The lips and ears are blue, and the face is flushed. The patient is in a comatose state.

Fig. 174. The terminal stage. The lips and ears are most noticed by their deep purple hue; the face is less flushed than it was the day before. The patient may live another 12 to 24 hours.

Cyanosis due to *splenic polycythemia* (Fig. 515, p. 652) is slowly progressive, and the diagnosis is arrived at by finding in the patient a big spleen with **POLYCYTHÆMIA** (p. 650), and no other very definite lesion.

Cyanosis due to *inspissation of the blood* as the result of loss of fluid from the tissues in fevers, such as cholera, dysentery, yellow fever, or typhus, is a late symptom in a disease that will generally have been diagnosed upon other grounds.

Methemoglobinemia and *sulphhemoglobinemia* are diseases which have been grouped together under the term *enterogenous cyanosis*. Both are exceedingly rare. The tint of the skin by itself suggests the diagnosis, being altogether different from that of ordinary cyanosis, and yet not to be mistaken for pigmentary affections such as Addison's disease, argyria, ochronosis, or hæmochromatosis. There is no polycythæmia. The diagnosis is

established by spectroscopic examination of the patient's blood, a suitably diluted specimen exhibiting a well-defined absorption band in the red (*Fig. 22*, p. 13) in addition to the two bands of oxyhamoglobin between the D and E lines (*Fig. 17*, p. 13): the distinction between sulphamoglobin and methamoglobin is not easy except in the hands of experts in blood chemistry and spectroscopy. Some cases arise without any obvious external cause, and are to be distinguished from those in which the blood changes are directly

Fig. 175. Second day.

attributable to the effect of taking chlorate of potash, aniline derivatives, acetanilide, phenacetin, phenazone, and possibly other drugs. Some remarkable cases have occurred as the result of using brown boots polished with a preparation containing *oil of mirbane*, nitrobenzol, or nitrobenzene, the facies of the wearers becoming a remarkable blue-black colour for some time owing to the formation of methamoglobin in the blood: the damage may arise from simply wearing the shoes thus polished, the patient not necessarily being the polisher himself.

Herbert French.

CYSTINURIA is the term used to denote the presence of cystin ($C_3H_6NSO_2$)₂ in the urine. The latter is usually pale, turbid, slightly oily in appearance when passed, acid in reaction, with an aromatic odour resembling sweet-briar; after standing, alkaline decomposition leads to the formation of sulphuretted hydrogen and a change in colour from yellow to green. The cystin forms a light-yellowish deposit, which consists of colourless microscopic hexagonal plates (*Fig. 177*). The condition is hereditary, and is evidence of an innate peculiarity of metabolism which is not necessarily associated with departure from good health. The crystals have occasionally given rise to calculi of a light fawn colour when first passed or removed, changing to pale green on exposure to the air. Cystin is not dissolved on heating the urine or by adding acetic acid, but it is by mineral acids and by ammonia; one chemical test for it is to boil some urine with acetate of lead and caustic potash; if cystin be present a dark precipitate should form as the result of the formation of lead sulphide, but the best evidence of the condition is the discovery of the typical crystals in the urine microscopically.

Herbert French.

DAY-BLINDNESS. (See VISION, DEFECTS OF, p. 920.)

DEAD FINGERS. Most individuals are familiar with dead fingers arising in perfectly normal persons who have spent more than the usual length of time in a swimming bath or in the sea; sometimes all the fingers of both hands will go absolutely white under these circumstances; even the whole hand may go dead-white, but more often it is the fingers only. The toes may be affected in a similar way.

Similar deadness of the fingers results from exposure to cold on land, though the amount of cold required on shore is greater than that which produces dead fingers in the water; and the more inured the individual is, as the result perhaps of his occupation or other circumstances, the less easily do his fingers go dead with cold. This being so, it becomes a difficult point to decide just where deadness of the fingers ceases to be a physiological phenomenon and begins to be evidence of a pathological change. At the other end of the chain one has *Raynaud's disease*, one of the most characteristic of maladies, the patient's fingers going dead on the least exposure to cold, and sometimes often in quite warm weather. This phase of local syncope often passes on quickly to one of local asphyxia, in which the fingers and generally also the toes, from being white, go more or less purple or even quite black (*Fig. 266*, p. 320) and remain in this deeply cyanotic state for hours, days, or even weeks, unless artificial measures to restore the circulation are resorted to. In the most severe cases some portions of the affected tissues fail to recover their circulation properly, and die in patches, with the result that indolent ulcers develop, healing slowly to form depressed scars, and thus simulating to a minor extent the effects of frostbite. Even extensive gangrene and loss of fingers results sometimes.

A very similar condition in which dead fingers may be a symptom results from *ergotism* (p. 322); and deadness of the fingers may be one of the phenomena of *pellagra* (p. 279), although here erythema, followed by dark brown, almost black, pigmentation, is commoner than acute pallor. Fortunately both pellagra and ergotism are exceedingly rare in this country.

Between the physiological dead fingers of exposure in cold water or to cold atmospheres, and the pathological deadness resulting from Raynaud's disease as the result of exposure to temperatures which ought not to cause deadness of the digits in normal persons, one meets with varying degrees of precisely similar changes to which it is difficult to give an exact name. For instance, an apparently healthy individual complains that when he gets up on a winter's morning he finds that one or other of his fingers,

generally a ring or little finger, goes dead and white, and it is not until he comes down to breakfast and gets into a warm room with a fire that the circulation becomes restored in it; what name is one to give to this? There is no generalized syncope of all the fingers such as one meets with in Raynaud's disease; and yet the patient suffers from his dead fingers without any cause which should be adequate. The complaint is fairly common; generally it is no indication of disease. Five things in particular need to be thought of, however, before the trouble is put into the category of personal idiosyncrasy—namely: (1) *Cervical rib*; (2) *Excessive smoking of tobacco*; (3) *Arteriosclerosis*; (4) *Occupation*; (5) *Blue-brain*.

Deadness of the ring or little fingers may be one of the earliest symptoms in the case of a person who has a *cervical rib* (Fig. 440, p. 544). Later, more generalized neurotic symptoms in the arm and hand may be expected, or even atrophy of the muscles supplied from the ulnar part of the brachial plexus. Although the rib dates from birth, it is remarkable how it often produces no symptoms until adult life is reached; it may produce no symptoms at all even then; when it does so the patient's attention is seldom drawn directly to the neck, but nearly always to something being the matter with the hand or forearm, especially the ulnar aspect of the latter and the little and ring fingers. If one realizes that the cervical rib, or the fibrous band which joins the end of a buttress cervical rib (Fig. 441, p. 544) to the first rib, is liable to interfere with the lower trunks of the brachial plexus, one can imagine the various vasomotor and other nervous symptoms that may result; and if the possibility occurs to one, the diagnosis is established by means of the X rays. Only when in place of any bony rib there is but a fibrous cord representing it will these fail to show either the entire rib or, more commonly perhaps, a stump representing the vertebral end of such a rib, sufficient nevertheless to indicate the cause of the nerve symptoms in the hand and arm.

Any liability to dead fingers is accentuated by *excessive smoking*, especially of cigarettes and in those who inhale the smoke. The liability lessens or disappears after a time if smoking is given up.

Arteriosclerosis or *atheroma*, or both, may involve the vessels supplying the hands and produce in the latter various symptoms of deficient circulation, including dead fingers. The patient will generally be past middle life, and as a rule there will be other indications of arterial degeneration, especially raised blood-pressure, though when atheroma rather than arteriosclerosis is the cause, the arterial affection may be extensive though the blood-pressure is not raised. The condition in the arms and hands comes on as a rule spasmodically, or in paroxysms when the arms and hands are used, and the remarks made on page 441 in regard to intermittent claudication apply here just as they do in the case of the leg. Dead fingers from this cause, however, are not met with frequently.

Occupation as a cause for dead fingers is familiar in two classes of persons in particular—namely, in those whose hands are immersed for many hours a day in waters of different temperature, especially if there are chemical ingredients such as carbonate of soda in the waters—washerwomen for example; and in those who carry heavy loads upon one shoulder in such a way as to depress that shoulder and push the head far over towards the opposite side (p. 545). Apparently what happens is that the pushing asunder as it were of the shoulder and the neck throws much strain upon the fibres of the brachial plexus, and in some individuals this strain leads to degenerative changes which extend down the nerve of the arm into the hand; pains may be the most prominent result, generally most severe in the region of the shoulder and the upper arm, especially in the parts supplied by the circumflex nerve; in other cases, besides the pain, or without pain, muscular atrophy results; in a few instances vasomotor phenomena predominate, and dead fingers or even a condition similar to that of Raynaud's disease has resulted. That occupation is the probable cause will be suggested by the symptoms being so much more pronounced in one hand than in the other, for it rarely happens that the man will carry weights first on one shoulder and then upon the other, so as to affect both brachial plexuses alike.

Blue-brain is a descriptive term, coined by Goodhart, to cover a very extensive class of case in which all sorts of peripheral phenomena of a functional type have their root, in his opinion, not in a peripheral cause but in a central one; and as the individuals generally have what is called a poor circulation, with a tendency to blueness of the ears and hands, a

liability to chilblains and other phenomena of that kind, he considers that they also have a corresponding tendency to poorness of the circulation in the cerebral centres ; just as they have blue extremities, so they have, as he says 'blue-brain'. The patients are not all women, though the majority are ; they have aches here and pains there : the abdominal aorta is often unduly pulsatile : the right kidney is often movable : there is suffering at the monthly periods : the knee-jerks are exaggerated : the patients are of the nervous, neurotic, neurasthenic, or even actually hypochondriacal type. Amongst the many symptoms that they complain of, deadness of the fingers on the slightest provocation may be one : the condition may then simulate Raynaud's disease, and it is a question whether in Raynaud's disease itself the vasomotor anomaly is not central rather than peripheral. Every practitioner has met with dead fingers in patients for whom they can recognize at once that the term 'blue-brain' fits as an appropriate label : for a full description of the types of case in question he should read Goodhart's original paper upon the subject.

Herbert French.

DEAFNESS has many causes : in most cases both ears are affected, though one ear is frequently deafer than the other, or one may be apparently normal some long time before it is involved. In a small proportion of cases deafness is strictly unilateral. The seeds of deafness are often sown in childhood, when it is easily overlooked ; treatment at that time holds out hope of cure, whereas deafness recognized for the first time in adults is apt to be progressive and resistant to treatment.

Cases of deafness resolve themselves into three main groups, namely : (1) *Central deafness*, due to lesions of the brain, especially of the temporosphenoidal lobes, resulting from congenital defects, as in some cases of deaf-mutes ; or from acquired lesions caused by syphilis, cerebral softening, hemorrhage, or tumour. (2) *Internal deafness* from lesions in the internal ear, in the cochlea, or in the auditory nerve. (3) *Conduction deafness* due to lesions in the conductor structures concerned in conducting impulses to the auditory nerve. In investigating each case, the first thing is to decide whether the lesion lies in the conducting media or in the auditory nerve and its terminations.

The Organ of Hearing. This lies in the temporal bone and is arbitrarily divided into two parts for clinical purposes : (1) a part concerned with the conducting of sound vibrations to (2) the essential perceptive organ the cochlea which contains the terminations of the auditory nerve.

1. *The conducting portion* consists of the external auditory meatus, the tympanic membrane, the ossicles—malleus, incus, and stapes, this last lying in the foramen ovale of the vestibule and so transmitting the sound vibrations to the endolymph of the inner ear—and on the inner wall of the middle ear a second path for vibrations, the foramen rotundum. An all-important adjunct to the conducting apparatus is the Eustachian tube. This tube connects the middle ear with the nasopharynx : at each act of swallowing it opens and allows the air to gain access to the ear, thus maintaining an equal pressure on the inner and outer sides of the tympanic membrane.

2. *The perceptive portion* consists of the cochlea and auditory nerve : the terminations of this nerve are disposed in a special end-organ, the organ of Corti. This apparatus is called the inner ear, as opposed to the middle ear. The vibrations that have arrived at the oval and round windows are transmitted to the endolymph, the fluid that fills the inner ear, and so to the organ of Corti.

The rest of the inner ear is occupied by the semicircular canals, which are concerned with equilibration : in many affections of the cochlear portion of the inner ear the canalicular portion is also involved, so that deafness and vertigo are frequently associated.

Tests of Hearing. In order to relegate cases of deafness each to its correct group certain tests are applied, and these tests are directed for the most part to investigating the reaction of the ear to musical notes, produced usually by tuning-forks : such tests show the quality rather than the quantity of the hearing.

1. *The Whispered Words Test.* This is made in order to discover the amount of hearing present : each ear is tested separately, and the distance at which words are heard is noted. The examiner must use a whisper constant in intensity. It will be found that patients suffering from conducting deafness—due to a lesion in the conducting apparatus—will hear words of high pitch such as those containing sibilants (six, sister) much better

than those of low pitch (mother, murmur, uncle); whereas in the case of patients whose deafness is caused by a lesion of the internal ear—nerve deafness—the reverse will be true. It is important to be sure that the opposite ear is thoroughly excluded, and this may involve the use of Bárány's apparatus, a clockwork device for making a noise in the ear.

2. *The Watch Test.*—A watch may be used instead of the voice, but it is not so satisfactory.

3. *The Lateralizing Test (Weber's Test).* A vibrating tuning-fork placed on the head in the middle line is normally heard equally in either ear: should one ear be affected by conducting deafness, the fork is heard better in that ear: should the case be one of internal-ear deafness, the fork is heard better in the ear that hears whispered words more plainly.

4. *The Relative Air-Bone Test (Rinné's Test).* A vibrating tuning-fork is held alternately with its prongs opposite the external meatus and with its stem on the mastoid process. Normally the note is heard some time longer opposite the meatus after it has ceased being heard through the bone: this result is expressed as air-bone conduction or as a 'positive Rinné'. If the case is one of conducting deafness the result of this test is reversed, the fork is heard better through the bone, and the result is expressed as a 'negative Rinné'.

If the case is one of internal deafness the result is 'positive'.

5. *The Lower-Tone Limit Test.*—The range of hearing is considerable: it reaches at the lower end to a note of 16 double vibrations per second, while at the upper end it has been variously estimated, but is roughly 20,000 vibrations per second. In cases of conducting deafness the ability to hear low notes disappears, in other words the 'lower-tone limit' is raised. In cases of internal-ear deafness the lower-tone limit remains normal.

Fig. 178. The monacord.

(Illustration lent by Messrs. J. & W. Baker.)

6. *The Upper-Tone Limit Test.*—There are two methods of testing the upper end of the range of hearing, one with Galton's whistle, the other the monacord. Galton's whistle is essentially a fine organ pipe which can be altered in length by means of a plunger, and on to this pipe air is blown from a small bulb: it is a difficult instrument to use satisfactorily. The monacord is simpler to use, and has the great advantage that it can be standardized easily: it consists of a length of about 50 cm. of steel piano wire (gauge 26) fixed on a metal frame: on the frame slides a 'bridge' through which the wire passes (Fig. 178): when the wire is thrown into longitudinal vibrations (by rubbing with wool moistened with methylated spirit) it gives out a high note, and the shorter the wire the higher the note. The effective length of wire is determined by the position of the bridge: if all the component parts are standard, the actual number of vibrations produced is immaterial, and the highest note heard is expressed in terms of length of wire. Normally the highest note heard is that produced by 14 or 15 cm. of wire.

7. *The Absolute Bone-conduction Test.*—This test compares the patient's hearing of a tuning-fork held on the bone—either on the mastoid or on the middle line of the head—with that of a normal individual. In cases of syphilitic nerve deafness or of nervous exhaustion the duration of audibility by bone conduction is shortened.

One may sum up the results of the tests in the two main types of deafness as follows:—

In cases of conducting deafness: the lateralization is to the affected side, bone conduction is better than air conduction (Rinné negative), perception of lower tones is lost, the upper-tone limit is not much changed, bone conduction is not changed or may perhaps be increased.

In cases of internal deafness: lateralization is towards the better ear, air conduction

is better than bone conduction (Rinné positive), the lower-tone limit is normal, the upper-tone limit is depressed, bone conduction is less than normal.

It is by no means easy to fit all cases of deafness into one or other of these two groups : often the results point to the case being a mixture of middle- and internal-ear deafness. Otosclerosis has some special features : lateralization is to the affected side, Rinné's test gives a strongly negative result, the lower-tone limit is markedly raised, the upper-tone limit is often depressed, but the bone conduction is shortened ; further, paracusis Willisii, or ability to hear better in a noise (in a tram or train), is quite frequent.

Conducting Deafness. Efficient examination of the ears will demonstrate the cause in most cases. One needs to inspect the auricle, the external auditory meatus and canal, and the tympanic membrane ; and since infection of the ear through the Eustachian tube plays so large a part in many cases of deafness, one needs to test the Eustachian tube itself, and also to examine the general state of the teeth, gums, mouth, palate, fauces, tonsils, pharynx, posterior nares, and nose.

The auricle and external meatus may be involved in a diffuse inflammation of the soft parts so severe as to obstruct the meatus completely ; or there may be blockage as the result of perichondritis of the auricle, or from the effects of injury. The external auditory meatus or canal may be obstructed by wax, foreign bodies, boils, exostoses, stenosis, polypi, or growth.

The tympanic membrane may show perforation, a tear or split, granulations, various degrees of inflammation, scars. Normally the tympanic membrane is of a pearly grey colour with a glistening surface : the projection of the handle of the malleus is seen as an oblique line running downwards and backwards, with a pale projection due to the short process of the malleus at its upper end. When inflamed the membrane becomes red and loses its glistening appearance ; subsequently the malleus becomes invisible and the whole membrane bulges ; later, if pus forms in the tympanum, a part of the membrane may bulge more than the rest and appear yellow. In certain cases of recent deafness (e.g., following a cold in the head) the membrane becomes indrawn, the malleus assuming a more oblique position, and the tympanum may be definitely concave : such a condition is due to blockage of the Eustachian tube, with resulting absorption of air from the tympanic cavity. Inflation of the Eustachian tube by politzerization or the catheter will restore the membrane to its normal position.

Internal-Ear Deafness or Labyrinthine Deafness of the type answering to the tests mentioned above is due to changes in the cochlea, including the fluid in the scala tympani and vestibuli, the organ of Corti, and the terminations of the auditory nerve and the spiral ganglion. Often the deafness is accompanied by tinnitus and sometimes by vertigo ; the symptom-complex of deafness, tinnitus, and vertigo is spoken of as Ménière's symptom-complex. Amongst the chief causes of internal-ear deafness are :

Certain febrile diseases, especially *mumps*, *influenza*, *scarlet fever*, *malaria*, *typhoid fever*. Mumps may be followed by complete permanent deafness in one ear. This type of deafness is probably due to toxæmia, in which case it is analogous to cases of deafness from toxæmia due to *septic teeth* or *tonsils*.

Some drugs are credited with the power of producing nerve deafness : *quinine*, *salicylates*, *tobacco*.

Certain *occupations* are responsible for internal-ear deafness : it is met with amongst *boiler-makers*, *caisson workers*, *aeroplane pilots*, and *wireless operators*.

Labyrinthine concussion, as experienced in the war, and in those who practise *revolver* and *rifle shooting*.

Previous middle-ear deafness predisposes to the deafness of the occupational and concussion groups.

Fractures through the *temporal bone* result in partial or complete nerve deafness.

Syphilis, acquired or congenital. Deafness of acquired syphilis may come on soon after infection or be delayed for years ; that of congenital comes on commonly about the age of twelve years, but is sometimes delayed until as late as forty ; it is almost always preceded by an attack of interstitial keratitis, and the cloudy cornea is most helpful in diagnosing the cause of severe deafness of this kind.

Familial cases of partial nerve deafness are known which answer to the same tests

as cases of acquired internal-ear deafness : several members of a family may be unable to hear the notes of bats and birds.

Hæmorrhage into the inner ear : this is rare, though it is met with sometimes in certain blood diseases, such as *leukæmia* or *pernicious anæmia* : or in association with hæmorrhagic conditions associated with *purpura* : the deafness thus produced comes on suddenly and is accompanied by severe disturbance of the semicircular canals, the condition being known as the *apoplectiform type of Ménière's disease*.

Nerve Deafness.—This term may be reserved for cases in which the auditory nerve is itself involved in some lesion that destroys its function. An *acoustic nerve tumour*, for instance, or fibrosis after *cerebrospinal meningitis*, or callus after *fracture of the skull* involving the petrous bone. Such lesions lead to total deafness on the side affected, with complete loss of labyrinth function (see VERTIGO, p. 911).

W. M. Mollison.

DEFORMITY OF THE CHEST. Many slight deviations from the average form of the chest are not produced by disease. A long narrow *alar* chest, or a flat chest with markedly diminished antero-posterior diameter, seems predisposed to phthisis : but they also occur in individuals who do not develop consumption. A long neck and sloping shoulders also tend to phthisis, while short, thick necks with high shoulders prevail in persons subject to apoplexy, though cerebral hæmorrhage may occur in patients of any type of build and many with thick short necks die of something else. There is no rule : merely a predisposition.

The alterations in the form of the chest which result from disease may be considered under the following headings : (1) *Deformities the result of rickets* : (2) *General changes* in the form of the chest : (a) The barrel-shaped, (b) Unilateral enlargement, (c) Unilateral shrinking : (3) *Local changes* : (a) Bulging, (b) Retraction.

1. Rickets.—The chest tends to become pear-shaped on transverse section (*Fig. 179*), with prominence of the sternum and flattening on either side of the latter, even to the extent of producing the 'pigeon-chest' appearance (*Fig. 181*). Beading of the costochondral junctions of the ribs gives rise to the 'rickety rosary'. *Harrison's sulcus*, a horizontal groove in the lower part of the rickety chest, is due to the pulling in of the ribs along a line corresponding with the attachments of the diaphragm. These deformities are associated with signs of rickets elsewhere in the child (p. 182).

Sometimes a chest is so deformed that the adjective 'crumpled' might almost be applied : there may be a deep hollow of the lower end of the sternum : or some ribs may stand out prominently whilst others look crushed together : or the whole chest may look twisted and awry, without evident cause : it is doubtful if all such deformities are invariably rickety, for many seem due to defective attitudes in childhood, the result perhaps of sitting at table or at school-desks on stools that are too low, or of sitting for long periods in crumpled attitudes in chairs. Attitudinal deformities are not necessarily rachitic.

2. General Changes.

a. The Barrel-shaped Chest is found in patients suffering from *pulmonary emphysema* (*Fig. 182*). The chest gives the appearance which is assumed by the normal chest only on exaggerated inspiration. The antero-posterior diameter is greatly increased. The shoulders are higher and squarer than in health, the intercostal spaces widened, the dorsal curve of the spine exaggerated. The movements of the chest during respiration are extremely restricted : there is elevation of the chest as a whole during inspiration, but very little real expansion : in many healthy young males there is a difference of over 5 in. between maximum and minimum chest measurements, but with emphysema the difference between the inspiratory and expiratory circumferences may fall to less than 1 in. The neck appears abnormally short. The apex beat of the heart cannot be felt, and the heart may be difficult to hear. The percussion note over the lungs is hyper-resonant, the cardiac dullness diminished or even indistinguishable, the upper level of the hepatic dullness lowered. The breath-sounds are enfeebled, inspiration is shortened and expiration prolonged. If bronchitis be present also, adventitious sounds are heard, especially sonorous and sibilant rhonchi.

b. A Unilateral Enlargement of the chest can be produced by an extensive *pleuritic effusion*, a large *empyema*, *pneumothorax*, and when an *intrathoracic tumour* affects the greater part of one side of the chest. The cause of the enlargement is ascertained by the

physical examination. Thus, with *pleuritic effusion*, either serous or purulent, the movements of the affected side during respiration are restricted, while those of the opposite side are exaggerated; dullness is found over the effusion, while above it the note is usually of higher pitch than normal, and often skodaic; vocal fremitus, breath-sounds, and voice-sounds are diminished or absent over the dull area; at the upper level of the fluid ægophony may be present, and the breath-sounds frequently tubular. The presence of fluid is further confirmed by finding the heart pushed over to the opposite side, and the liver depressed when the right pleura is involved. When a *pneumothorax* is present, there is usually a history of a sudden onset, accompanied by a severe pain in the chest; the affected side does not move as freely as the other with respiration; the heart is displaced towards the opposite side; vocal fremitus and breath- and voice-sounds are diminished or absent, though the affected side of the chest is fully resonant; if serum or pus be present in addition to air, the note is dull or greatly impaired at the base of the lung, with hyper-resonance but absence of breath-sounds above. When much fluid is present, the note changes considerably with the position of the patient. The metallic tinkling of Laennec

Fig. 182. Emphysematous chest.

Fig. 183. Fibrosis of the left lung—man, age 50 years.

FIGS. 179-183.—CYTOMETRIC TRACINGS OF VARIOUS FORMS OF CHEST.

Tracings of various forms of chest at the level of the sternoclavicular articulation, reduced from cytometric tracings. The dotted lines indicate the natural shape at the same age. The figures represent the measurements in inches. (*Stewart's Physical Signs*.)

is sometimes heard over a pneumothorax; coughing is generally required for its production; it resembles the sound which occurs when a drop of water falls on the surface of a fluid contained in a half-filled cask. The bell sound or 'bruit d'airain' is characteristic of a pneumothorax; to hear it, auscultation is performed over a portion of the pneumothorax, while a coin placed on another portion is struck with a second coin; the sound has a ringing metallic quality like that of the tinkling of a small bell, or like the ring that accompanies hammering upon a blacksmith's anvil. Hippocratic succussion may also be obtained when the observer's ear is applied to the chest while the patient's body is shaken or jolted. X-ray examination may assist materially in differentiating one type of intrathoracic lesion from another, and particularly in detecting intrathoracic new growth—pulmonary or mediastinal.

Whenever loss of symmetry in the two sides of the chest is found, the vertebral column should be examined carefully, for the alteration may be due to lateral curvature of the spine, and not to intrinsic chest changes.

c. *Shrinking of the whole of one side of the chest* is generally due to contraction of one lung, either as the result of a previous compression by a large pleuritic effusion, and especially by an empyema, or on account of *fibrosis of the lung* (Fig. 183). The history of

the patient often indicates the cause of the contraction of the lung : a large effusion may have been aspirated, or an empyema may have been drained by surgical means, leaving the scar of the operation. In other cases the empyema may have burst into the lung, and there may be a history of a large amount of pus having been expectorated. With fibrosis of the lung the affected side is retracted and shrunken, the intercostal spaces are narrowed, and the ribs may even overlap. The shoulder is lower on the side that is affected, and the vertebral column is deviated towards the diseased lung. The heart is drawn over to the affected side, in which there is deficient movement during respiration. If the left lung be affected, the heart will be less covered by lung than normally, and so there may be a large area over which cardiac pulsation is visible. The note over the contracted lung is impaired, while on the opposite side it is hyper-resonant. The breath-sounds are deficient or absent, and may be tubular or cavernous, while at the base there may be numerous coarse bubbling râles, especially if there is bronchiectasis. Vocal fremitus may be decreased or exaggerated. The expectoration is generally copious, purulent, and often fetid. There is often marked clubbing of the tips of the fingers.

3. Local Changes.—

a. The cause of *bulging* of any portion of the chest wall may be difficult of diagnosis, though sometimes it is obvious, as when an *empyema* points externally ; even this is sometimes mistaken for a localized abscess of the chest wall, unless a careful examination reveals the sign of fluid within the chest. Curiously, an empyema points as a rule, not at the base behind, as one might expect, but either in the second or third intercostal spaces below the clavicle in front, or else in about the fifth or sixth intercostal space between the nipple and the anterior axillary lines. In *pulmonary emphysema* bulging is often present in the supraclavicular and infraclavicular regions. Bulging may also be due to an *intrathoracic tumour*, to an *aneurysm of the aorta*, or to a *tumour or abscess of the chest wall*. The most common situation on the chest wall for an aneurysmal swelling is to the right of the sternum in the first, second, and third intercostal spaces ; it may erode the upper part of the sternum and so produce a swelling there, while in rare instances it may produce a prominence to the left of the sternum ; a bulging to the left of the vertebral column may be due to an aneurysm of the descending thoracic aorta. The expansile character of the pulsation suggests the diagnosis. A tumour or abscess of the chest wall or of a rib may occur in any situation ; the commonest varieties are those due to tuberculous cold abscess, to secondary cancer deposits, to gummata in tertiary syphilis, or to multiple myelomata.

The precordia becomes prominent in children in cases of *pericardial effusion*, or when the heart is affected by valvular disease or adherent pericardium of old standing so that, by reason of the cardiac enlargement, the soft ribs of the child have been moulded outwards, as it were, by the long-continued pressure of the big heart against them : the situation of the prominence indicates its cardiac origin. *Enlargement of the liver* may produce a prominence of the ribs under which it lies, and a *hydatid cyst* may first attract attention in this way ; a hepatic abscess, a subdiaphragmatic abscess, or an empyema, sometimes points over the lower part of the chest in front, while a psoas abscess may point over the lower ribs posteriorly. A prominence over the spinal column in the dorsal region may be due to *spinal caries*, or to a *malignant new growth of the spine*. An angular curvature of the spine is most commonly due to spinal caries, and any swelling which is associated with it may be produced by an abscess arising from the disease. Bulgings which give an impulse on coughing, and which wax and wane with respiration, suggest *hernia of the lung*, sometimes of considerable size in marasmic children suffering from whooping-cough, or in emaciated phthisical subjects with incessant cough.

b. *Retraction* or localized shrinking of the chest wall occurs in any condition in which there is a portion of lung contracted by disease. When present over one or both apices of the lungs, as shown by retraction in the supra- and infra-clavicular regions, it is nearly always due to *phthisis*, though in this malady, in its early phases particularly, local wasting of the chest wall is due less to shrinking of lung tissue than to trophic atrophy of the muscles overlying the foci of active disease in the lung ; this local atrophy of muscles recovers, and the deformity disappears, when the phthisis abates or is cured. Unilateral shrinkage is also found with *fibroid conditions of the lungs* which are not tuberculous, or after the absorption of a pleuritic effusion or the removal of the pus from an empyema. The

commonest cause of local retraction of the chest wall, however, elsewhere than at one or other apex, is deformity due to irregularity of development, or to the effects of postural errors during development.

Herbert French.

DELIRIUM is a symptom of disordered function of the higher portions of the central nervous system, and it may be due to so many different types of causes that, taken by itself, it generally has but little diagnostic importance, though it gives rise to much alarm amongst the patient's friends and to anxiety to the physician. It is rather of prognostic than of diagnostic significance, as a rule; and in most cases the cause is arrived at by reason of other features of the case—the history of alcoholic indulgence, the pyrexia, the co-existence of physical signs of lobar pneumonia, the presence of albuminuria and a high blood-pressure, and so on. If one is called to a case in which the primary symptom is delirium, it may be necessary to watch the case a little while before one can decide between such things as hysteria, acute encephalitis, belladonna poisoning, heat-stroke, cerebral malaria, drink, a fractured skull; but if the history can be obtained clearly, and a routine examination of all the systems be made, it is less difficult as a rule to come to a conclusion as to the nature of the delirium than it is to describe all the differential diagnostic points in detail: the temperature; evidence of paresis; inequality of the pupils; widely dilated pupils; urine analysis; and in the obscurer cases examination of the cerebrospinal fluid obtained by lumbar puncture, are amongst the more important things affording clues. The various causes may be classified as follows:—

Delirium due to Fevers:—

Typhoid fever	Lobar pneumonia	Infective endocarditis
Typhus fever	Capillary bronchitis (late stage)	Sapraemia
Malaria	Measles	Septicopyaemia
Yellow fever	Scarlet fever	Septicæmia
Cholera	Small-pox	Suppurative pyelephlebitis
Relapsing fever	Chicken-pox (severe types)	Suppurative cholangitis
Spirochaetosis icterohaemorrhagica	Pertussis (severe type)	Suppurative osteomyelitis
Dysentery	Acute pulmonary tuberculosis	Erysipelas
Influenza		Glanders.

Delirium due to Approaching Death: whatever the cause.

Delirium due to Kidney Affections (Uræmia):—

Acute parenchymatous nephritis	Secondary to cystitis (ascending nephritis), especially in association with: Enlarged prostate; stricture of the urethra; retention of urine with overflow as the result of nerve diseases such as tabes dorsalis, compression	paraplegia, disseminated sclerosis, combined sclerosis of the cord, fracture dislocation of the spine, primary lateral sclerosis
Chronic parenchymatous nephritis		Tuberculous kidney
Chronic interstitial nephritis		Stone in the kidney.
Coli bacilluria		
Infective pyelonephritis		

Delirium due to Acidosis:—

Diabetes mellitus	Cyclical vomiting of children	Severe vomiting of pregnancy.
-------------------	-------------------------------	-------------------------------

Delirium due to Water Starvation:—E.g., the madness of those who have been without water for days after shipwreck, or in scorching deserts.

Delirium due to Acute Blood-loss:—

Severe HÆMATEMESIS (q.v.)	Post-partum hæmorrhage	Intraperitoneal hæmorrhage, as after rupture of an ectopic gestation.
Severe HÆMOPTYSIS (q.v.)	After stabs or wounds	
Severe MELÆNA (q.v.)		

Delirium due to Parasites in the Circulating Blood of the Venous System:—

Trichinosis	Trypanosomiasis (sleeping sickness)	Malaria (cerebral or maniacal type).
-------------	-------------------------------------	--------------------------------------

Delirium due to the Bites or Stings of Reptiles, Fish, etc.:—

Adder bites	Tarantula bites	Poisoning by puncture of the skin by the fin-spikes of sea-cat and weaver fish.
Venom from tropical snakes	Jelly-fish stings	
Scorpion stings	Hornet, wasp, and bee stings	

Delirium due to Intrinsic Brain Lesions :—

Encephalitis lethargica
 Acute encephalitis
 Acute cerebellar ataxy
 Acute streptococcal meningitis
 Acute pneumococcal meningitis
 Acute staphylococcal meningitis
 Acute typhoidal meningitis
 Acute paratyphoidal meningitis
 Acute anthrax meningitis
 Acute meningococcal meningitis

Acute tuberculous meningitis
 Acute influenzal meningitis
 Acute 'meningismus' (i.e., a condition which is probably mild meningitis of pneumococcal, influenzal, streptococcal, or other variety, insufficient in degree to kill, and therefore often undiagnosed as to its precise nature)
 Otitis media with local non-suppurative meningitis
 Lateral sinus thrombosis

Cavernous sinus thrombosis
 Cerebral syphilis
 Acute delirious mania
 Acute mania
 Dementia præcox
 Dementia senilis
 General paralysis of the insane
 Cerebral malaria
 Cerebral tumour
 Cerebral hemorrhage
 Cerebral embolism
 Cerebral thrombosis
 Hydrophobia
 Botulism.

Delirium due to Severe Head Injury :—

Concussion : (a) As an initial symptom ; (b) As a symptom during recovery

Fractured skull

Meningeal hemorrhage.

Delirium due to Poverty in the Cerebral Circulation :—

a. Owing to old age—the muttering night-delirium of old age
 b. Owing to chronic anæmia, as in : Pernicious anæmia, aplastic anæmia, spleno-medullary leukaemia, lymphatic leukaemia, splenic anæmia, ankylostomiasis, lymphadenoma, chloroma, septic anæmia, extremely slow convalescence

c. Due to low blood-pressure, as in Addison's disease, and after severe hemorrhage
 d. With extreme plethora, as in : Splenomegalic polycythæmia, congenital heart disease
 e. With failing heart, as in the terminal stages of mitral stenosis, fibroid heart, and myocardial changes of any kind

f. With Cheyne-Stokes breathing from any cause : notably with softening of the medulla oblongata : the delirium is pronounced at the height of the respiratory curve, when the patient may writhe in bed, throw the arms about, groan, moan, or shout, though perfectly placid in the apnoeic interval.

Delirium due to the Immediate Action of Certain Drugs :—

a. Drugs which generally produce delirium if taken in excessive doses, yet short of causing coma and death : Belladonna, atropine, stramonium, hyoscyamus, daturine, hyoscyne, cocaine, cannabis indica, aconite, camphor
 b. Alcohol, taken in large quantities at one sitting, especially if in the form of spirits on an empty stomach

c. Drugs which anesthetize when taken in larger quantities, but which cause delirium sometimes : chloroform, ether, nitrous oxide, opium, morphia
 d. Drugs which cause delirium only in susceptible individuals : caffeine, guarana, lupulus (hops), santonin, quinine, salicylates
 e. Drugs which cause general body-reaction when they are

given by injection, probably related to protein shock : Horse serum, antistreptococcal serum, antidiphtheritic serum, antimeningococcal serum, anti-anthrax serum, antidysentery serum (Shiga), salvarsan injections and its allies, peptone injections, colossal manganese injections, colossal selenium injections, antimony injections.

Delirium due to the Continued Deleterious Action on the Nervous System of Certain Substances taken by the Mouth :—

a. Alcohol ('delirium tremens' of the soaker or drunkard)
 b. Lead : 'Saturnine encephalopathy' and its protean symptoms simulating various other types of brain disease or insanity

c. Manganese : manganese poisoning is met with mainly in workers in manganese ores : in acute cases there may be permanent central nervous system changes simulating combined scleroses

of the cord with ataxy and nystagmus
 d. Seleniuretted hydrogen : met with in those who use paints of which this is an ingredient.

Delirium due to Gases of Various Kinds :—

a. Products of incomplete combustion of coal-gas
 b. Products of incomplete combustion of petrol
 c. Products of incomplete com-

bustion of coke in ovens and stoves
 d. Gaseous emanations from lime-kilns

e. Various gases produced in the complex processes of many modern trades.

Delirium due to the Sudden Stopping of a Drug Habit :—

Alcohol

Morphine

Heroin

Cocaine.

Delirium due to Animal Bites :—

Hydrophobia (rabies) : Dogs, foxes, wolves

Rat-bite fever (spirochaetosis) : Rats, ferrets, mice, cats, weasels, stoats.

Delirium due to Excessive Heat :—

Heat-stroke (in the stage preceding coma).

Delirium due to Liver Diseases (Cholæmia) :—

Any form of JAUNDICE (q.v.)

Aeroplane dope poisoning

Phosphorus poisoning

when it is long-continued

Infections of the liver : Chole-

Antimony poisoning

Acute yellow atrophy of the liver

cystitis, cholangitis, pyle-

Cirrhosis of the liver

T.N.T. (trinitrotoluol) poisoning

phlebitis, tropical abscess,

hydatid disease

Delirium due to Dilated Stomach from Pyloric Stenosis :—

Due to tetany and uræmia (see below).

Delirium due to Poisonous Foods :—

False mushrooms (poisonous

ally even eggs or milk, in

Potomac poisoning

toadstools of various kinds)

particularly susceptible indi-

Botulism.

Crabs, strawberries, occasion-

viduals

Delirium due to Hysteria.

It would take a great deal of space, and unnecessarily, to discuss each item of the above list *seriatim* ; circumstances will suggest the diagnosis nearly always if the possibilities are borne in mind, careful inquiries as to history are made, and careful examination of the patient is carried out. Few special remarks seem called for here, but amongst such are the following :

Malaria merits particular comment because the symptoms of cerebral malaria may be mistaken all too easily for either some form of general insanity such as mania or dementia, or for a gross vascular intracranial lesion such as cerebral hæmorrhage, the opportunity for saving the patient's life by quinine injections being let slip. Cerebral malaria of extreme degree arises seldom in those who have been long absent from malarious districts : it is met with in the latter, but may also occur in patients now in England but not long since returned from the west coast of Africa, or from India, or even from certain parts of Italy. The cause of the cerebral symptoms is blockage of the cerebral capillaries by myriads of the malarial hæmatozoa in the blood, and the diagnosis rests upon discovery of some of these hæmatozoa in stained blood-films. The diagnosis will be suggested by the geography of the patient's recent movements : though difficulties might arise if he were a chronic drunkard, with a bad family history of insanity, so that the need for blood-films might escape notice in view of the apparently obvious, though wrong, diagnosis of either delirium tremens or of alcoholic insanity of maniacal delirious type. In the tropics the condition may be mistaken for heat-stroke.

Gross Intracranial Lesions may be simulated by various of the other causes of delirium : but light on the diagnosis may be thrown by lumbar puncture and examination of the cerebrospinal fluid (p. 382) : lumbar puncture is probably justifiable in most cases of delirium in which the cause may be in doubt without it.

Diabetic Delirium is less common than is diabetic coma, to which it is usually a precursor ; the sweet acetone-like odour of the breath and the glycosuria would seem to be easy tests of the condition : but it is noteworthy that several other causes of delirium may simulate diabetes by giving rise to glycosuria, or at any rate to a condition in which the urine reduces Fehling's solution as though glycosuria were present, for the time being. Many 'drunks' show this phenomenon : so also do many who have had head injuries or concussion. It is not perfectly safe, therefore, to assume that a delirious person is a diabetic simply because glycosuria is discovered : and the diagnosis may remain in doubt until opportunity arises to watch the case and to re-test the urine after an interval.

Poisons as a cause for delirium may be easy to diagnose if there is collateral evidence from the history, or from the contents of bottles found near the patient ; very difficult sometimes if there is no such guidance. Belladonna is the commonest purely deliriant drug, perhaps, and it is suggested partly by the excessive wideness of the patient's pupils,

partly by the curious semi-purposefulness of the patient's actions in his delirium: he may incessantly but tremulously go through, in dumb show, the movements of some such act as picking fruit from a tree, or trying to shave himself, or trying to thread an imaginary needle with an imaginary piece of thread: similar actions may be seen in certain cases of delirium tremens, but they are seldom so sustained as they may be in belladonna poisoning.

Delirium Tremens may be almost characteristic; the chief difficulty as a rule is to tell how much of the delirium in a given case is due to previous drinking habits alone, and how much is the result of the added effects of acute pyrexial illness, lobar pneumonia for instance, or of severe injury, such as a severe fracture of the leg. In true delirium tremens the patient can often talk quite sensibly if only the subject is changed at very brief intervals: if the same subject is kept before him for more than a minute or so he wanders off and shouts or becomes violent, seeing imaginary objects and reacting in various ways to what he thinks he sees: in the delirium of disease the power to talk sensibly in connection with constantly changing subjects is less pronounced.

Saturnine Encephalopathy appears to be the result of gross brain-cell changes caused by the long-continued action of small quantities of lead in the system: instead of getting peripheral neuritis and wrist-drop the patient gets more or less brain paralysis instead. He may simulate delirium tremens, or dementia, or general paralysis of the insane, or acute mania or melancholia—the symptoms are protean. His occupation, or other indications that he has been exposed to the effects of lead (p. 45), may make the diagnosis probable: but some cases are inevitably missed. The importance of attributing the symptoms to their correct cause may be great in connection with the Employer's Liability Act or Workmen's Compensation Act: quite apart from the fact that it is less slur on other members of the family if the symptoms can be attributed to a definite cause like lead instead of to some less definite form of insanity.

Dilated Stomach with Pyloric Stenosis, especially when the lesion has been an ulcer in the past, is well known as a cause of tetany: it is less familiar, perhaps, as a cause of delirium, and even of coma and convulsions—indeed of symptoms which are identical with those of chronic and acute uræmia. The condition is related in some obscure way to actual uræmia, for there may be a rise of the blood-urea from the normal maximum of 40 mgrm. per 100 c.c. to figures double this, or even to over 100 mgrm. per 100 c.c., even when there is no decided evidence of concomitant renal disease. What the precise relationship is between pyloric stenosis with gastrectasis and blood-urea accumulation with tetanoid or uræmic symptoms is uncertain, but cure of the stomach state by gastro-jejunostomy may lead to disappearance of the high blood-urea figure and of the delirium and other uræmic symptoms, so that it is important to recognize this rather rare, and yet not entirely uncommon, variety of delirium and get it treated promptly by gastric surgery: the modern view of its causation is that it is due to alkalosis—the converse of acidosis.

Herbert French.

DERMATITIS.—(See VESICLES, p. 913.)

DIACETURIA, or the passage of diacetic (aceto-acetic) acid in the urine, occurs under precisely similar circumstances to ACETONURIA (p. 3). The usual clinical test for it is to take about one inch of urine in a test-tube and add liquor ferri perchloridi (B.P.) drop by drop: for a moment a white precipitate of iron phosphate forms, and then, if aceto-acetic acid be present, the liquid becomes deep purple-red, this colour being discharged on warming (*Fig. 184*). If salol, aspirin, salicylates, carbolic acid or any of its compounds are being taken, the urine contains phenyl compounds which give a similar reaction with ferric chloride, but the colour due to these does not disappear on warming.

Herbert French.

Fig. 184.
Ferric chloride
reaction of diacetic
acid in urine.

DIARRHŒA. Diarrhœa is a symptom and not a disease in itself, and in every case one must try to discover what the underlying cause of the looseness of the bowels is. In order to do this it may be necessary, in addition to routine physical examination in the

ordinary way, to employ one or all of the following special methods : (1) Digital examination of the rectum ; (2) Inspection of the lower colon by the sigmoidoscope ; (3) Investigation of gastric digestion by test meals (see p. 400) ; (4) Examination of the stools by the naked eye and by the microscope. Most of these methods require no special description, or have been dealt with in other articles, but some account must be given of the examination of the stools.

Various 'test diets' for the investigation of the intestinal functions have been proposed, but it is sufficient to let the patient include the following articles in the dietary for about forty-eight hours before the stool is examined : (1) Milk ; (2) Eggs ; (3) Meat in some form ; (4) Farinaceous foods, e.g., bread, potatoes, rice ; (5) Green vegetables and stewed fruit ; (6) Fats, e.g., butter, bacon, fat, ham, etc. The choice and amount of the individual articles may be left to the patient's taste.

In order to *examine the stool*, a portion the size of a walnut should be rubbed up with normal saline solution to a fluid consistency, and examined with the naked eye against a dark background. Normally one sees a homogeneous fluid made up of very small dark-grey particles. In pathological conditions one may recognize mucus, pus, blood, parasites, the remains of connective tissue in the form of yellowish-white shreds, brown muscle fibres, and the residue of potatoes in the form of glossy granules.

For *microscopical examination* one prepares three specimens. The first is examined as it is ; to the second one adds a few drops of 30 per cent acetic acid, and heats a little to dissolve fat ; to the third is added a little iodine solution.

A normal stool shows in the first preparation a few muscle fibres, some yellow lumps of lime salts, and a few empty potato cells. In the second preparation, a few fatty crystals ; in the third, a very few violet-tinted starch grains. In pathological conditions one may find in the first preparation many well-preserved muscle fibres, numerous fat droplets and fatty crystals, and abundance of potato cells ; in the acetic acid preparation, numerous masses of crystals of fatty acids ; in the iodine preparation, an excess of starch.

In order to *test for bile*, mix some of the stool with concentrated corrosive sublimate solution and allow to stand for twenty-four hours. Normally it turns red from the presence of urobilin ; greenish particles show the presence of unaltered bilirubin ; absence of green or red colouring shows that bile is not present at all.

Reaction of the Stool. A drop of the stool prepared as above by rubbing up with water is applied to a glass rod to a piece of moistened litmus paper. The reaction can be seen best on the other side of the paper. A normal stool is nearly neutral ; marked alkalinity indicates putrefaction ; acidity shows carbohydrate fermentation.

Test for 'Occult' Blood. The patient must have eaten no red meat for two or three days. A portion of the stool the size of a hazel-nut is rubbed up with 2 c.c. of distilled water and placed in a test-tube. Add half its volume of glacial acetic acid, and shake. Then nearly fill the tube with ether, and reverse several times. To about one inch of the resulting yellow, translucent, ethereal solution, add : (a) a few drops of glacial acetic acid, (b) one inch of *freshly prepared* saturated solution of benzidin in rectified spirit, (c) one inch of liq. hydrog. perox. Shake, and pour a few drops on to a porcelain slab. If blood is present, a blue colour appears.

DIARRHŒA IN INFANCY AND EARLY CHILDHOOD.

1. **Acute.** The acute diarrhœas of infancy are either dyspeptic or infective in origin. The infective diarrhœas are usually spoken of as 'summer' or 'epidemic' diarrhœa. It is often impossible to distinguish sharply between the simple dyspeptic and the infective variety, but it may be said that the greater the signs of toxæmia (collapse, sinking in of the fontanelle, inelasticity of the skin), the more likely is it that the case is one of infection. High body temperature and epidemic prevalence of the disease are also in favour of such a diagnosis. Dyspeptic diarrhœa may be due to mal-digestion of any of the constituents of milk. Examination of the stools may enable one to distinguish which constituent is at fault, thus :

Stools containing white tough particles, insoluble in alcohol and ether mixture -
casein indigestion.

Green slimy stools containing small granular masses soluble in alcohol and ether
mixture fat indigestion.

Frothy sour stools sugar indigestion.

Green stools are of no special diagnostic value, as they merely indicate that the contents have been hurried unduly through the intestine.

If the stools contain visible blood and mucus, and are passed with much pain and straining, *acute colitis* may be diagnosed, but not until *intussusception* has been excluded (see BLOOD PER ANUM, p. 96).

2. Chronic.—Chronic diarrhœa in infancy may follow upon an acute infective diarrhœa or be dyspeptic from the outset. The history and a consideration of the points mentioned above will determine the diagnosis in most cases, but it must be remembered: (1) That an intestinal catarrh set up by an infection may lead to mal-digestion and persistent chronic diarrhœa in consequence: and (2) That a dyspeptic diarrhœa predisposes to the development of intestinal infections. The two classes may therefore pass into each other and an exact differential diagnosis be impossible.

There is a special form of chronic diarrhœa in early life which follows a very prolonged course, and to which the term 'celiac disease' or 'the celiac affection' is applied. It usually starts in the second or third year of life, and is characterized by the passage of stools which are not very frequent but are bulky, pale, and extremely offensive, containing much undigested fat and free fatty acids. The abdomen is tumid and tympanitic, and the child wasted and stunted in growth and development. This form of diarrhœa is very apt to simulate abdominal tuberculosis, and indeed is usually diagnosed as such: but in abdominal tuberculosis enlarged glands or a rolled-up and thickened omentum may perhaps be felt, or there is ascites or evidence of tuberculosis elsewhere. Sometimes, however, a diagnosis is only possible after watching the progress of the case.

If the stools in a case of chronic diarrhœa contain visible mucus and blood, and are passed with much straining, special involvement of the large bowel may be diagnosed (chronic colitis). The history will usually point to a preceding attack of acute colitis.

DIARRHŒA IN ADULTS.

1. Acute.—The history is of great importance. It may elicit some *indiscretion of diet* (the eating of unripe fruit, etc.), or the consumption of some toxic article of food (*ptomaine* or '*food poisoning*') or irritant drug (e.g., arsenic). In such cases vomiting is often present as well. In toxic cases there is great depression, and a feeble and, perhaps, irregular pulse. If there is fever one should think of an infective cause, such as typhoid fever, or dysentery. In the case of *typhoid*, enlargement of the spleen is an early confirmatory sign, but is sometimes absent: spots should also be looked for. The presence of leucopenia may be of help, and the pulse-rate is low in proportion to the temperature. The agglutination reaction is not usually obtainable until after the end of the first week. In *dysentery* there will be tenesmus, with blood and mucus in the motions. In the amoebic form, the *Entamoeba histolytica* may be found in the stools, and the character of the multiple small pitted ulcers seen through the sigmoidoscope is almost pathognomonic. In the specific form, the blood serum agglutinates Shiga's bacillus. Similar symptoms to those of dysentery are produced by *acute colitis*, especially of the ulcerative form.

Appendicitis may begin with acute diarrhœa, and the possibility of this should be borne in mind.

In *pernicious anæmia*, *exophthalmic goitre*, and *Addison's disease*, periodic attacks of acute diarrhœa are apt to occur. The other characteristic signs and symptoms of these affections will be present.

Finally, it should be remembered that even although diarrhœa is due to a new growth in the bowel, it may begin acutely, and a rectal examination should never be omitted.

2. Chronic. Chronic diarrhœa in the adult may be the result of several causes, of which the following are the chief:—

Impaired Gastric Digestion (gastrogenic diarrhœa). The looseness tends to occur in bouts, with intervals of freedom. The stools contain fragments of connective tissue and show under the microscope an excess of unaltered muscle fibres. A test meal reveals absence or great diminution of gastric juice (achylia). This form of diarrhœa often occurs in Addisonian (pernicious) anæmia. It can be controlled by doses of dilute hydrochloric acid.

Impaired Pancreatic Digestion (pancreatic diarrhœa).—The stools are pale or white in colour, very offensive, and show, on cooling, solidified fat masses: microscopically they exhibit excess of fat globules and fatty acid crystals along with undigested muscle fibres and starch granules. There may be a very high diastase coefficient in the urine: instead of lying between 6 and 20 the figure may be even as high as 300. (See also CAMMIDGE'S PANCREATIC REACTION, p. 128.)

Local Conditions in the Colon :

a. Faecal Impaction (paradoxical diarrhœa). This variety is commonest in elderly persons. Rectal examination reveals retained faeces, and faecal masses may perhaps be felt through the abdominal wall. A thorough evacuation arrests the discharges.

b. New Growth. There is nothing absolutely characteristic about this form of diarrhœa, but the motions are often explosive and tend to occur in the early morning. Blood may be present in the stools, but not always. Digital examination of the rectum or the use of the sigmoidoscope will reveal a growth. It should be noted specially that neither a sudden beginning of the symptoms nor the youth of the patient excludes the possibility of growth.

c. Chronic Catarrh of the Colon or Rectum.—The diarrhœa in this variety tends to be in the early part of the day ('morning diarrhœa'), the stools are well-digested, and may or may not show visible mucus. Examination with the sigmoidoscope will show a catarrhal condition of the mucous membrane if the disease affects the pelvic colon. In cases in which the chief seat of the affection is higher up it may only be possible to arrive at a diagnosis by the method of exclusion.

d. Ulcerative Colitis. The stools are frequent, usually small, often passed with some straining, and contain visible mucus, blood, and shreds. The sigmoidoscope reveals ulceration of the mucous membrane. The ulceration may be dysenteric or non-dysenteric in nature, but the history will usually enable one to make the distinction. Bacteriological examination of the stools and the serum reaction of the blood may be conclusive.

Catarrh of the Small Intestine. The stools are usually copious, fluid, free from visible mucus or blood, unless the colon is involved as well, and show under the microscope impaired digestion of all the food constituents and the presence of bile-stained particles of mucus. Sometimes the diagnosis can be arrived at only by exclusion. If catarrh of the small intestine is diagnosed, one has to determine its cause. The chief things to think of are : cardiac disease or cirrhosis of the liver producing chronic venous stasis in the bowel ; phthisis or other forms of tuberculosis ; chronic nephritis ; alcoholism ; and the ingestion of irritants (e.g., arsenic, antimony).

Lardaceous Disease is a rare cause of chronic diarrhœa nowadays, and is not likely to occur unless there be signs of waxy disease elsewhere, e.g., in the spleen, liver, or kidneys. There may be a history of prolonged suppuration or tertiary syphilis. Chronic ulcerative colitis may itself be a cause of lardaceous disease.

Tropical Diseases. The two chief tropical diseases causing chronic diarrhœa are, besides chronic dysentery already mentioned, *sprue* and *hill diarrhœa*.

In sprue the pale, frothy, and copious stools are characteristic, besides the presence of a painful stomatitis involving the tongue and lining membrane of the mouth. It should always be thought of as a possibility in the case of a patient who has lived in the East.

Hill diarrhœa, which is closely allied to sprue, is met with chiefly in Europeans on their going to the hills after living in the tropical lowlands. The diarrhœa tends to occur chiefly in the early morning, the stools being copious, pale, and frothy. The diarrhœa is accompanied by much flatulence and distention.

Nervous Causes. If all the above causes of a chronic or recurring diarrhœa can be excluded, one may be dealing with a case of *nervous diarrhœa*, which is characterized by a tendency for the bowels to act directly after a meal (lientery) or on excitement or under emotional influences. A good many cases of so-called 'morning diarrhœa' are of this type, though in many there is a catarrhal basis as well. The history, the presence of other evidences of nervous irritability, and the fact that the general health and nutrition are well maintained, all yield confirmatory evidence. Frequent action of the bowels may accompany *tabes dorsalis*, either in a late stage when sphincter trouble has arisen, or earlier in the form of *rectal crises* analogous to the more familiar gastric crises of this disease.

Robert Hutchison.

DIAZO-REACTION.—The diazo-reaction of Ehrlich is obtained in certain urines on testing them with the following solutions :—

(1) Sodium Nitrite	-	-	-	0.5	grm.	(2) Sulphanilic Acid	-	-	-	0.5	grm.
Distilled Water	-	-	-	100	c.c.	Hydrochloric Acid	-	-	-	0.5	c.c.
						Distilled Water	-	-	-	100	c.c.

A strong solution of ammonia is also required, and all should be freshly prepared. To a drachm of sulphanilic acid solution add a drop of sodium nitrite solution, mix with a drachm of the urine, and add ammonia to excess. A normal urine turns brownish-yellow; when the reaction is positive the mixture turns deep red, and, most characteristic of all, the froth produced on shaking the test-tube is rosy red.

It is often regarded merely as an obsolete test for typhoid fever; but it occurs in many other conditions: it is an indication of abnormal protein metabolism, leading to the elimination of certain aromatic substances which react in this way to diazo compounds. The following are some of the conditions under which the diazo-reaction has proved positive: Many fevers, such as diphtheria, erysipelas, measles, pneumonia, scarlet fever, typhoid, typhus; cachectic states, such as advanced phthisis, cancer, cirrhosis, syphilis, malaria, grave anemias; and in poisoning by certain drugs, such as chrysarobin, guaiacol, carbolic acid, or opium.

Clearly a reaction which occurs under so many different circumstances can have but a limited value. There are some who say that it has no value at all. Others, however, find it of clinical use in the following respects: (1) It is never normal; (2) It is more constantly present in cases of typhoid than in any other fever, so that, other things being equal, the presence of the diazo-reaction may help in diagnosing typhoid fever, though the converse is not true; (3) In cases of phthisis a positive diazo-reaction is a sign of ill omen, whilst should the diazo-reaction disappear after it has been present, this is evidence of material improvement, even though the physical signs remain the same. *Herbert French.*

DILATATION OF THE HEART.—(See ENLARGEMENT OF THE HEART, p. 257.)

DILATATION OF THE STOMACH presents itself clinically under two totally different aspects: (1) *Acute*; (2) *Chronic*.

1. Acute Dilatation of the Stomach is generally a serious complication, or often rather a fatal catastrophe, arising in the course of some other condition, especially:

After operations, notably laparotomy, performed for whatever cause	In the course of acute fevers, especially lobar pneumonia
After abdominal injury	In the course of chronic heart failure, especially in bad cases of mitral stenosis.

The diagnosis is generally easy; it is the relief of the acute dilatation that is so difficult. The blown-up, drummy abdomen, the constant effort to bring up wind, sometimes in vain, sometimes with copious and recurrent eructations, often with ominous hiccough, are familiar and much to be dreaded. Sometimes shortly before, sometimes just after, death immense quantities of blackish-brown or dull greenish-brown fluid flow from the mouth and nostrils, and the wonder is how it can all be coming from one stomach. The dilatation itself is of the nature of acute paralysis of the gastric walls, and the final outflow of fluid—which gushes out rather than is vomited—is caused by the pressure of the gas associated with it, and not by active contractions of the stomach musculature.

2. Chronic Dilatation of the Stomach is due to totally different causes, which may be divided into two main groups, namely:—

i. *Those associated with stenosis at or on either side of the pylorus, due to:*

Cicatricial fibrosis of an old simple gastric ulcer			
Cicatricial fibrosis of an old duodenal ulcer			
Adhesions around or near the pylorus, the result of former local peritonitis due to such causes as: Former gastric ulcer; former duodenal ulcer; gall-stones. In many cases adhesions are found without any ascertainable cause			
Carcinoma of the pylorus	Carcinoma of the duodenum	Carcinoma of the gall-bladder	Carcinoma of the head of the pancreas
Rarities, such as calcified retroperitoneal cyst; hydatid cyst at the portal fissure; huge renal or suprarenal tumour.			

ii. *Those due to dilatation without obstruction:*—

Atony. Over-distention by gas or excess of food or drink.

In the consulting-room the two most suggestive signs of dilatation of the stomach are: (a) A gastric succussion splash, audible or palpable over a much wider area than normal. The mere presence of succussion is not an indication of dilatation, for a normal stomach

containing fluid and gas gives marked succussion. The point to determine is the area over which the succussion is heard; and if it extends right across the epigastrium and down to the umbilicus, or below it, when the patient is lying down, dilatation is almost certain. (b) Visible gastric peristalsis over an unduly large area.

Formerly it was considered that the most important symptom of pyloric stenosis was the vomiting at relatively long intervals of larger quantities of material than were consumed at the last meal, especially if remains of a meal taken the day before could be recognized in the vomit; but it is known now, as the result of early examinations with X rays after bismuth or barium meals (*Fig. 185*), that such vomiting may only set in as a late sign, years after the stenosis has originated; the patient complaining merely of periodic acute indigestion, flatulence, distention, and discomfort of a type which, but for X-ray examination, might well be regarded as simple flatulent dyspepsia. The importance of early X-ray examination in all cases of persistent indigestion is beyond doubt, for verification of the diagnosis by curative operation has demonstrated again and again that a marked degree of pyloric or duodenal stenosis, with extensive dilatation of the stomach, may be present in a patient who never vomits at all. If the bismuth meal is taken at 10 a.m., none should be seen in the stomach at 6 p.m. Very often in these cases, however, the black shadow is still seen in the stomach eight hours after the meal was given (*Fig. 186*), and sometimes even after twenty-four hours. If, at the first X-raying, the stomach is obviously large, yet vigorously peristaltic, and if, eight hours later, there is

Fig. 185. Skiagram of the stomach a quarter of an hour after a barium meal in a case of pyloric stenosis due to fibrous ulcer. The stomach is of great size, the gastro-traites taking the form of elongation rather than of dilatation.

Fig. 186. The same case as *Fig. 185*, eight hours after the barium meal. Notwithstanding powerful gastric peristalsis, there has been great delay in the emptying of the stomach; by this time the whole of the barium should have been in the caecum and colon, whereas actually the greater part of the bismuth is still in the stomach, small quantities only having passed on through the pylorus into the small intestine. Pyloric stenosis was confirmed at operation, gastrojejunostomy being performed.

still a considerable amount of bismuth in the pyloric third, the probability is that the dilatation is stenotic and that operative treatment is indicated. Skiagraphy is infinitely superior to any other method of diagnosis in these cases, and is replacing diaphany, lavage, inflation, and gastric-juice analyses wherever available, and by its means it is often possible to detect such difficulties as hour-glass stomach, or to distinguish ulcer from carcinoma. Once dilatation from stenosis has been demonstrated in this way, operative measures are indicated, for medicinal treatment cannot cure the mechanical stasis. The further details of the diagnosis are arrived at by the surgeon: even when the abdomen has been opened, however, it is often exceedingly difficult to decide whether a given hard mass at the pylorus is malignant, or due to inflammatory matting round an old simple ulcer, and it may remain in much doubt which of the two is present until one finds that the patient either develops metastatic deposits in the liver, lymphatic glands, peritoneum, or elsewhere; or alternatively survives for years after his gastro-enterostomy and thus demonstrates that what was thought at the time to be a carcinoma must after all have been not malignant, but the result of inflammatory matting round a simple chronic ulcer. Broadly speaking, the greater the dilatation of the stomach, the more likely is the stenosis to be non-malignant; often, indeed, malignant stenosis of the pylorus is associated with relatively little gastrectasis, whereas fibrous stenosis of pylorus or duodenum may lead to so much dilatation that gastric succussion may be audible over the greater part of the abdomen.

DIPLOPIA, or double vision, may be either monocular or binocular; that is to say, an object may be seen double with one eye, or single with each eye separately and only double when both eyes are open. To distinguish between the two conditions it is necessary that each eye should be closed in turn. If with either eye the object is still seen double, the diplopia is monocular and due to that eye alone; if, on the other hand, the object is seen double only when both eyes are open, the diplopia is binocular, and due to some disturbance of the balance of the two eyes.

Monocular Diplopia may be due to: (1) Dislocation of the lens; (2) Incipient cataract; (3) Double pupillary apertures; (4) Low degrees of astigmatism.

In a case of monocular diplopia it is necessary to examine the eye by light reflected upon the pupil from an ophthalmoscope mirror in a dark room. Diplopia from a *dislocated* or *displaced lens* will only occur when the edge of the lens is in the pupil, some rays passing outside the lens direct to the macula, and other rays, passing through the edge of the lens, being deflected to a different part of the retina. In these circumstances the edge of the lens will be seen in the pupil as a dark crescentic opacity of unmistakable form and appearance. Other symptoms which may serve to confirm the diagnosis are increased or irregular depth of the anterior chamber (the space between the iris and the cornea), and tremor of the iris during movements of the eye.

Early *cataract* usually leads rather to the appearance of multiple images than of two only, a candle or light being seen as five or six. This polyopia is due to the fact that the lens is broken up by cortical cracks and opacities into sectors of varying refractive power, often set in slightly different planes. These cracks and sectors of the lens are seen as black radial opacities on illumination by an ophthalmoscope mirror, or as opaque white striae when the eye is illuminated from the front by a lens.

The presence of *two pupillary apertures* will be apparent at once on a careful examination of the eye. They may be congenital, or due to accident or operation. In cases of diplopia due to multiple pupillary apertures the double vision is most evident when the object looked at is not in accurate focus.

Should none of the three conditions mentioned above be found it is most likely that the diplopia is due to a *low degree of astigmatism*. In this condition letters and test types are often seen accompanied by faint 'ghosts' placed either above or to the side of the real letters, and in some cases overlapping them. This cause of monocular diplopia can be determined only by careful examination of the refraction of the eye. The diplopia is cured by the wearing of suitable glasses.

Binocular Diplopia may be either: (1) Physiological, or (2) Pathological.

Physiological diplopia occurs unnoticed in all normal binocular vision. It is evident that as the two eyes view any given object from different standpoints, the retinal images must differ as do the two views taken by a stereoscopic camera. The diplopia is not apparent, however, as the two dissimilar images are combined by the higher visual centres of the brain to form a single solid conception of the object viewed. The amount of dissimilarity of the retinal images gives the impression of space and distance, near objects causing images more unlike than those formed by things remotely placed. The dissimilarity of the two retinal images in normal binocular vision, giving the idea of space, is termed in psychology 'disparateness' or 'disparation'.

When, however, owing to some failure in the centre which controls the mental fusion of the two ocular images, they are not combined, or when some disturbance of the accurately balanced muscular mechanism upsets the automatic fixation of both eyes upon the same object, pathological or obvious diplopia results.

Pathological Diplopia.—Before discussing the various forms and causes of this condition it is necessary to have a clear idea of the visual process of localizing objects in space—projection, or orientation.

In normal binocular vision, looking at an object means that both eyes are so turned that the image of the object looked at falls upon the central most acute area of the retina, the macula or yellow spot, in each eye, and objects other than that directly looked at form images upon the retina which are more or less peripheral. From our experience of such sensations and their locality on the retina we are able accurately to determine the relative positions of objects in space. The image of any object falls upon corresponding areas of the retinae of the two eyes. These areas, though always

corresponding, are not in the true sense of the word symmetrical. The image of an object to the right of the eyes falls upon the nasal side of the right and the temporal side of the left retina; but the corresponding areas are in normal circumstances always stimulated simultaneously, and from these retinal images is derived the idea of the position of the object in space.

If the normal relative position of the two eyes is upset in any way the image of an object no longer falls upon two usually corresponding areas, erroneous ideas of projection are formed, with consequent diplopia, and it is from an examination of this diplopia that we can ascertain the displacement of the eye and its probable cause.

For example, *Fig. 187* represents diagrammatically a condition in which the left eye is looking at or fixing the object *O*, while the right eye is pointing abnormally inwards—a convergent strabismus. In consequence of the abnormal position of the right eye, the image of the object *O* does not fall upon the yellow spot on the macula, *f*, but upon a point internal to it, *a*. In ordinary circumstances, with proper fixation of the two eyes, any

Fig. 187. Homonymous double images.

Fig. 188. Crossed images.

object whose image fell upon *a* would be to the right of the object *O*, hence under the existing abnormal conditions the right eye erroneously projects the object *O* to the position *O'*, and a diplopia results in which the right of the two images seen belongs to the right eye, and the left to the left eye. This is termed a homonymous diplopia. *Fig. 188* shows in a similar manner the formation of a crossed diplopia in a divergent squint or strabismus. These two figures illustrate the formation of a diplopia in lateral deviations of the eyes. A moment's consideration will show that deviation in a vertical or oblique plane will equally cause diplopia, owing to the disturbance of the normal corresponding areas of the two retinae.

It will be seen from the figures that, in lateral deviations, a convergent squint causes homonymous, and a divergent squint crossed, diplopia. In ocular paralyses the diplopia will increase if the two eyes are carried in the direction of the usual action of the paralysed muscle. As an example, *Fig. 187* may be chosen as a diagrammatic representation of a paralysis of the right external rectus muscle. The more the eyes are turned to the right the greater will be the convergence, owing to the inability of the right eye to turn to the right to the same extent as the left: the greater therefore will be the diplopia as the image of the object *O* falls farther and farther round on the nasal side of the right retina, the object being projected farther and farther to the right. It will also be seen from this consideration that in a case of diplopia from a muscular paralysis, when the eyes are carried as far as possible in the direction of the usual action of the paralysed muscle, the farthest displaced image always belongs to the paralysed eye.

The two images are not equally distinct; that in the unaffected eye falls upon the macula and is seen most distinctly—the *real image*; that falling upon the retina of the affected eye is more peripheral, and therefore not so definite; it is termed the *false* or *apparent image*.

With the above considerations in view, and with a knowledge of the individual actions of the ocular muscles, it is easy to elucidate cases of simple paralysis of one or more ocular

muscles, but for convenience of reference the chart giving the position of the images in paralysis of the various ocular muscles is reproduced below.

Binocular diplopia may be caused by paralysis of any ocular muscle, but it may also arise from the bodily displacement of one eye from such causes as *orbital growth, abscess, hæmorrhage, or cavernous sinus thrombosis*; it may also occur after *tenotomy*.

Left-sided
Paralysis.

The dotted lines represent the apparent image.

Right-sided
Paralysis.

External Rectus.

Diplopia appears in looking toward the paralysed side.
The lateral separation of the images increases as the paralysed eye is abducted.

Internal Rectus.

Diplopia on looking towards the sound side.
The lateral separation of the images increases in adduction of the paralysed eye.

Superior Rectus.

Diplopia on looking up.
The vertical distance between the images increases as the paralysed eye is elevated and abducted.
The obliquity increases in adduction.
The lateral separation of the images diminishes when the eyes are turned laterally in either direction.

Inferior Rectus.

Diplopia on looking down.
The vertical distance between the images increases as the paralysed eye is depressed and abducted.
The obliquity increases in adduction.
The lateral separation of the images diminishes when the eyes are turned laterally in either direction.

Superior Oblique.

Diplopia on looking down.
The vertical distance between the images increases as the paralysed eye is depressed and adducted.
The obliquity increases with the abduction.
The lateral distance between the images diminishes when the eyes are turned laterally in either direction.

Inferior Oblique.

Diplopia on looking up.
The vertical distance between the images increases as the paralysed eye is elevated and adducted.
The obliquity increases with the abduction.
The lateral distance between the images increases as the eye is elevated and abducted.

Fig. 189.—To ILLUSTRATE THE BEHAVIOUR OF THE DOUBLE IMAGES IN PARALYSIS OF THE OCULAR MUSCLES.

Cases of displacement of the eye from local causes can usually be distinguished from those of ocular paralysis by the indeterminate character of the diplopia, which is accompanied by more or less fixation of the eyeball, and by proptosis.

Isolated paralyzes of individual ocular muscles or groups of muscles are nearly always nuclear in origin; basal growths rarely cause ocular paralyzes of any extent on one side only, the affection sooner or later becoming bilateral.

In some rare cases of convergent or divergent squint with absence of binocular vision and good vision in each eye, there may be the power of alternate fixation with more or less evident diplopia. As a rule, however, the individual has the power of suppressing the image of the squinting eye, obtaining monocular vision.

Diplopia is probably the commonest symptom of *lethargic encephalitis*, a disease in

which any function of the central nervous system may be disturbed. The slightest disturbance of balance in the function of the ocular muscles is quickly perceptible to a patient in the form of diplopia—a fact which goes far to explain the frequency of this symptom. Not uncommonly the earliest, perhaps the only, evidence of encephalitis is the occurrence of diplopia associated with malaise, slight pyrexia, and headache, the whole syndrome being regarded as ‘influenza’ or as a transient ailment of no serious import. Unfortunately it often happens that serious sequelæ follow, the most striking and frequent of which is post-encephalitic Parkinsonism. In other cases diplopia is accompanied by serious disturbances in relation to other cranial nerves, and sometimes by cerebral symptoms such as hemiplegia or hemianopia, and the constitutional disorders may be more severe. High fever, excruciating headache, and mental aberration may be prominent symptoms in the early stage of the disease, and the diagnosis may depend on the elimination of other diseases, especially meningitis, cerebral abscess, or uræmia. Examination of the blood and cerebrospinal fluid is often necessary before a correct diagnosis can be arrived at. In patients suffering from encephalitis lethargica the pressure of the cerebrospinal fluid is usually raised, and the liquid is either clear or tinged with blood. There is often an increase of cells, lymphocytes, up to 100 per c.mm.; the amount of protein is within normal limits and the glucose content is generally raised. Other symptoms associated with encephalitis are various involuntary movements which may be choreiform, tremulous, or myoclonic. In the later stages, especially in conjunction with the Parkinsonian syndrome, the patients may complain of great restlessness, lack of initiative, salivation, attacks of dyspnoea and hiccough, dysphagia, and general slowness in carrying out all the ordinary activities of life. In children, particularly, the acute phases of the disease may be followed by morbid changes in moral and mental calibre, and the tendency to be wakeful at night and sleepy during the day may be prolonged for months or even years.

Diplopia is a common symptom in the rare disease *botulism*, produced by the ingestion of the *Bacillus botulinus*. The diplopia may be masked by ptosis, and is usually accompanied by mydriasis, dysphagia, dysphonia, vomiting, cramps in the limbs, and, especially in fatal cases, coma. The diagnosis generally depends on a history of one or more persons having partaken of a meal off some canned food and developing, at intervals varying from six to thirty-six hours, a combination of the symptoms just described. The disease generally occurs, therefore, in small epidemics, and the diagnosis may be suspected before it is possible to confirm it by cultivating the bacillus from the remnants of food. Should any of the infected food have been thrown out into the poultry yard, the rapid mortality amongst the fowls may afford another clue to the nature of the malady.

Herbert L. Eason.

DISCHARGE FROM THE EAR. (See OTORRHOEA, p. 521.)

DISCHARGE, NASAL.—A discharge from the nose may be acute, subacute, or chronic, and it may consist of clear fluid almost like water, of mucus, mucopus, pus, food regurgitated through the nose, or blood. For the differential diagnosis of the causes of hæmorrhage from the nose, see EPISTAXIS, p. 273.

Regurgitation of Food through the Nose may be due to a congenital condition, especially *cleft palate*; to acquired *perforation* of the palate, especially *syphilitic*; to *post-diphtheritic paralysis*; or to much rarer neuromuscular lesions, such as *bulbar paralysis*, *pseudobulbar paralysis*, or *myasthenia gravis*, all of which are discussed elsewhere.

Serous, Mucous, and Mucopurulent Discharges differ from each other chiefly in degree, for that which may begin as serous may later become mucopurulent and then purulent, as is seen during the course of a common cold. A watery discharge is sometimes spoken of as *coryza*, though for the latter to be typical there should at the same time be watering of the eyes; it is generally acute in onset, and the diagnosis of its cause is not difficult as a rule. It may be due to the following different conditions:—

Common cold, early stage (<i>Micrococcus catarrhalis</i>)	Arsenic	Some cases of spasmodic asthma
Lachrymation	Local irritants such as snuff, ammonia vapour, sulphur dioxide, chlorine, and other irritating gases	Some cases of trigeminal neuralgia
Hay fever (<i>coryza v. feno</i>)		Neurosis (rhinorrhœa).
Measles	Fog	
Iodism or bromism		

The differential diagnosis of these conditions needs little discussion, a careful inquiry into the circumstances of the case generally pointing to its nature at once. *Measles* probably presents the greatest difficulty, for the coryza precedes the macular eruption, and the patient, generally a child, may seem to be suffering merely from a severe cold when in reality it is in the most infectious stage of measles. Examination of the buccal mucous membrane for Koplik's spots (*Fig. 190*) may sometimes serve to distinguish

Fig. 190. Koplik's spots.

this malady as long as two days before the skin eruption appears. These spots are individually small, with a whitish centre the size of a pin's head, surrounded by a purplish-red blush; in many cases they are not single, but collected into groups of from two or three to thirty or more; a common place to find them is on the inner aspect of the cheeks, in much the same position as that in which one expects to find brown pigmentation in Addison's disease; but they should be looked for also on the gums, the inner aspects of the lips, and on the hard and soft palates. Tiny flakes of curdled milk may be mistaken for them, but Koplik's spots cannot be swabbed off as milk curds can be.

The coryza resulting from *iodide* or *bromide of potassium* or from *arsenic* may be very severe, and the patient generally complains of constantly catching cold, when in reality the symptoms are due to the drug.

The term *influenza* is sometimes applied to severe febrile colds associated with running of the eyes and dripping at the nose, but it is often inaccurate to apply the term *influenza* here, for the symptoms are more often due to the *Micrococcus catarrhalis*. Bacteriological detection of the *Bacillus influenza* in the discharge is essential if influenza is to be diagnosed with accuracy.

Excessive secretion by the lachrymal glands apart from emotion may in some instances lead to constant dripping of water from the nose as the result of *neurosis*.

One rare form of watery discharge from the nose is the escape of *cerebrospinal fluid*; this is perfectly transparent, like water, and its nature is suggested at once if there is a history of the commonest cause for the symptom—namely, an injury to the head leading to fracture through the base of the skull involving one of the anterior fossæ. The fluid may drip steadily, at the rate of a certain number of drops per minute, and if it is collected in a test-tube it may be found to reduce Fehling's solution.

Purulent Discharge from the nose may result from that which has been in the first place serous, mucoid, or mucopurulent; or it may have been purulent from the beginning. If it is acute and bilateral it is probably due to a local infection by some pyogenic micro-organism, and even when it may seem to be due to nothing more than a common cold not a few different organisms may be discovered bacteriologically. Staphylococci, streptococci, and pneumococci are associated not at all infrequently with the *Micrococcus catarrhalis*. Influenza bacilli may be found. In rare cases, especially when the purulent discharge persists longer than it ought if it were the result merely of a cold, and especially in cases in which it is so acrid as to produce superficial excoriation and soreness of the edges of the nostrils and the upper lip, diphtheria bacilli will be found more often than might be expected. *Nasal diphtheria*, indeed, is not altogether uncommon,

but it is difficult to recognize except by bacteriological examination of the nasal discharge. The same applies to two very much rarer purulent lesions of the nose, namely, those due to *gonococci* and to *glanders*. There may be a urethral infection or a vaginal discharge to point to the diagnosis in the former case, the patient having transferred gonococci directly from the genital source to the nose by means of the fingers or a towel. Purulent rhinitis due to *glanders* is fortunately rare, though when it does occur it may escape recognition in its curable stage, unless the patient's occupation as a groom or horse-dealer suggests the source of the infection, or unless bacteriological methods are resorted to in all cases of nasal discharge that are not perfectly straightforward.

Chronic purulent nasal discharges are for the most part due either to lesions of the mucous membrane or to the emptying into the nose of purulent collections from the antrum of Highmore, frontal, ethmoidal, or sphenoidal sinus, or from necrosis of the nasal bones. The diagnosis may be obvious enough, but often it is by no means easy. It is essential that both nasal cavities should be inspected directly in a good light by means of a speculum and mirror; the various kinds of chronic rhinitis may be recognized in this way. In chronic *atrophic rhinitis* the amount of discharge is usually small, the cavities of the nose are relatively spacious, the smell offensive (*ozæna*), and there are generally crust-like deposits upon the mucous membrane. Chronic *hypertrophic rhinitis* may also produce a very offensive smell, a considerable purulent discharge, and difficulty or even inability to breathe through the nose owing to the bulging of the inflamed mucous membrane. There may or may not be *polypi* at the same time, and perhaps *adenoids* and *enlarged tonsils* owing to the necessity for breathing through the mouth. *Membranous rhinitis* is not a distinctive variety, it being more or less an accident whether the inflamed mucous membrane produces a membranous exudate or not; the discovery of membrane would suggest diphtheria, but bacteriological examination alone can determine whether the lesion is diphtheritic or not. *Syphilis* is responsible for a large number of the cases of *ozæna* and chronic rhinitis, especially of the atrophic form, but it is not responsible for all, and the diagnosis as to whether the lesion is syphilitic or not will rest upon concomitant signs elsewhere, upon the history, and upon the result of Wassermann's blood-serum reaction. Necrosis of the nasal bones, if it occurs spontaneously, is often syphilitic, but it may also result from an injury, such as a blow; the deformity which follows the falling in of the bridge of the nose is characteristic.

Tuberculous rhinitis is rare. There is a variety of nose affection called *rhinitis caseosa*, but this is acute and not tuberculous; the appearances might at first suggest that the nose was filled with a yellowish diphtheritic membrane, but on cultivation no diphtheria bacilli are to be found; what micro-organism is the cause of the cheesy exudate in these cases is not known; if left, the underlying mucosa is apt to ulcerate, but under simple antiseptic treatment cure results in a week or a little more. *Rhinoliths*, although they may cause persistence of a nasal discharge, are not in themselves a primary condition, but rather the result of preceding rhinitis. *Endothelioma*, *carcinoma*, or *sarcoma* affecting the nose is not common except as the result of direct spread to its interior from the lip, jaw, cheek, or forehead. Sometimes, however, considerable nasal discharge may result from the growth of a semi-malignant tumour known as *recurrent fibroma* or *fibrosarcoma* arising from the external periosteum of the basi-sphenoid bone, thus obstructing the back of the nose, and detected by a digital examination via the mouth.

A *foreign body* inserted into the nose by a child or by an insane person may produce damage associated with a purulent discharge, which may persist even after the foreign body has been detected and removed.

Lupus of the nose is hardly ever primary, and although it may destroy the margins and lead to a purulent discharge from the nostrils, the diagnosis is generally clear from the apple-jelly deposits in the adjacent skin of the cheeks. *Rodent ulcer*, on the other hand, though starting in the skin, may spread deeply into the nose, causing destruction of cartilage and bone, with pain and purulent discharge. Whereas *lupus* starts in early adult life, rodent ulcer begins at or after middle age. Histological examination may be required to distinguish it from *epithelioma*, though the latter is likely to fungate more and to have advanced more rapidly than rodent ulcer does; the latter may have existed for years without any rapid advance. Radium treatment, efficiently applied, will cure most rodent ulcers of the skin, but this therapeutic test is no longer applicable when the cartilages and

bones of the nose have become involved, for radium is then not able to cure the rodent ulcer any better than it can cure lupus or epithelioma.

Empyema of one antrum of Highmore may cause most troublesome purulent discharge from the nose, but it is not difficult to diagnose when the symptoms are definite. The patient generally complains that the pus invariably comes down one nostril; that it is associated with an odour which is offensive to himself in a way not common with ozæna generally; that he can often produce the discharge by tilting his head sideways in the opposite direction to that from which the discharge comes, and that he experiences dull aching pain in one side of the face, often spoken of as neuralgia, but upon investigation proving to be associated with tenderness located mainly in the corresponding superior maxilla. There may be a carious tooth, particularly a canine, from which infection of the antrum has taken place, though in a small number of cases a more serious cause exists, namely, carcinoma or endothelioma of the antrum, which can seldom be diagnosed until

Fig. 191. — Transillumination of the antra (Dr. Brown Kelly's method). *A* shows the normal appearance. *B* shows no illumination of the right side, owing to the purulent contents of the antrum of Highmore on that side.

an operation is undertaken or the growth itself begins to cause a protuberance either into the nose or through the face; the nature of these growths is determined histologically.

Examining the patient in a dark room by the introduction of an electric lamp into the mouth or posterior nares may reveal empyema of the antrum by transillumination of the superior maxilla of the normal side and opacity of the other in which the antrum is full of pus (*Fig. 191*).

Empyema of a frontal sinus has generally been preceded by acute nasal catarrh, which has led subsequently to severe aching above one or other eye, with tenderness on percussion over the affected frontal sinus, and so much pain in this region that the patient may be compelled to hold his head before he is able to cough or blow his nose, because of the increased pressure within this sinus due to either of these acts. The condition nearly always starts acutely, though if untreated it may become chronic and come under observation only when the infection has tracked its way through into the subcutaneous tissue so as to point above the eye or in the angle between the latter and the nose.

Suppuration in connection with the ethmoidal or sphenoidal sinuses can be little more than guessed at unless special skill has been acquired in the direct examination of these air-cells. If, however, there is a purulent discharge from the nose coming apparently from high up, in a patient who has neither antral disease nor infection of the frontal sinus, and in whom local conditions of the mucous membrane of the nose itself can be excluded, infection of the sphenoidal or of the ethmoidal cells is to be suspected. *Herbert French.*

DISCHARGE FROM THE NIPPLE. Discharges from the nipple may be divided into three classes :

1. Normal Discharges. It is quite natural for a woman during the period of pregnancy and lactation to have a discharge of milk from the breast. It is usually of small amount, except when the child is put to the breast, but occasionally the flow at other times may be sufficient to be distressing.

2. Normal Discharges at Abnormal Times. Milk may come from the breast at other times than during pregnancy and lactation. In infants it may be found as the result of undue stimulation on the part of the nurse, and it has been noted in the breasts of both sexes at the time of puberty. No great importance attaches to it.

3. Abnormal Discharges. *Blood or blood-stained discharge* is a significant sign which should never be neglected, for it almost always indicates the presence of some abnormal condition in the breast. The commonest is some growth involving the larger ducts in the neighbourhood of the nipple. This may be either innocent a *duct papilloma* : or malignant- *duct carcinoma*, *scirrhous carcinoma*, or *sarcoma*. It behoves one therefore never to neglect the sign. When a well-marked lump is felt the diagnosis can usually be made without difficulty, and for this the reader is referred to the article on SWELLING, MAMMARY (p. 837). Difficulty arises when there is no obvious swelling. In these cases the breast must be palpated carefully with the flat of the hand and also with the tips of the fingers, special attention being given to the part immediately subjacent to the nipple. If no swelling can be made out, and the bleeding remains a persistent sign, it may become necessary to make an incision into the breast for diagnostic purposes, recognizing the fact that a papilloma may be so delicate as to escape detection with the finger. Probably the commonest cause of bleeding is a duct carcinoma (columnar-celled carcinoma) ; after that, duct papilloma and scirrhous carcinoma : and, rarest of all, sarcoma.

A *purulent discharge*, or pus mixed with milk, generally indicates acute suppurative mastitis : the other signs of inflammation or abscess are well marked as a rule, so that there is no difficulty in arriving at a diagnosis. Chronic mastitis seldom causes a discharge of pus from the nipple, but the symptom is met with sometimes when the lesion is *tuberculous* ; the discovery of tubercle bacilli in the discharge will distinguish this from carcinoma, with which it is often confused.

A *discharge of serum* will suggest chronic interstitial mastitis with cyst formation, but the symptom is rare.

Hydatid fluid has been recorded as escaping through the nipple from a *hydatid cyst* of the breast, but it is so rare as to be a pathological curiosity. The nature of the fluid might be recognized by the finding of hooklets in it (*Fig. 76, p. 65*). *George E. Gask.*

DISCHARGE, URETHRAL. Any inflammatory process in the urethra causes a discharge. Although most commonly the result of infection by the gonococcus, by no means every urethritis is of this nature, and bacteriological examinations show that other organisms besides the gonococcus may produce a urethral discharge and the same symptoms as an acute gonorrhoea. Further than this, a purulent discharge may occur in which no micro-organisms can be found : for instance, when the urethra has been injured or subjected to irritation by the injection of strong solutions, or when it contains a foreign body, such as a calculus or a retained catheter. It is stated that a urethral discharge may be associated with *gout* and *rheumatism* : but although a few cases of the former have come under my care, I have been unable to prove that the small amount of discharge was not the remains of a former un cured urethral infection, or that it was directly due to the same source as the arthritic symptoms.

There is no doubt that an acute urethritis may be caused by other organisms than the gonococcus, and sometimes there is considerable trouble in completely curing it.

These cases may cause complications in the genito-urinary organs similar to those due to the gonococcus, such as prostatitis, epididymitis, or cystitis. They may arise by the infection of the urethra by septic instrumentation, or after connection with a woman subject to leucorrhœa. A careful bacteriological examination should always be made; more than once the reputation of a wife has been at stake until it was proved that the husband's urethritis was of staphylococcal and not gonorrhœal origin. An acute urethritis may accompany a hæmatogenous urinary infection; for instance, an acute pyelitis due to *Bacillus coli* may be followed by acute cystitis, prostatitis, and urethritis, in which no other organism but *Bacillus coli* can be found.

Gonorrhœal Urethritis is due to the infection of the urethra by the gonococcus of Neisser. In form it is a diplococcus with flattened surfaces approximating each other; it stains readily with basic aniline dyes, but differs from other diplococci in being decolorized by Gram's stain. The gonococcus is seen in a stained specimen to be *intracellular*, penetrating not only the leucocytes but also the epithelial cells found in a smear preparation, and, though the cocci may be found also between the cells, their appearance in the cells is strong evidence of their specific nature.

In any case presenting a purulent discharge from the urethra it is necessary, in order that appropriate treatment may be carried out, to ascertain the extent of the infection, not only in the urethra itself, but also in the other organs of the genito-urinary apparatus. For the purposes of clinical investigation the urethra is divided into anterior and posterior portions, separated by the membranous urethra, the anterior comprising the bulbous and penile urethra, and the posterior the prostatic portion. A urethritis is also, according to its clinical aspect, acute or chronic, the acute form being characterized by a thick, creamy, purulent discharge, with pain, and the chronic by a thin, greyish, mucopurulent discharge. Acute gonorrhœa affects not only the superficial layers of the urethral mucous membrane, but also the subepithelial tissues and the glandular elements, causing a leucocytic infiltration. The tendency of the inflammation is to spread backwards along the canal so that the prostatic urethra may become infected even in the acute stage, though most frequently this occurs at a later period; the prostatic and the ejaculatory ducts may become infected, and the inflammation may spread to the seminal vesicles, epididymes, or testes. In the acute stages of the disease the infection of the anterior urethra is accompanied, as a rule, by redness of the external meatus, scalding pain during micturition, and painful erections; occasionally all pain is absent, especially in patients previously infected with gonorrhœa. If the anterior urethra be irrigated with sterile water or saline solution the urine passed immediately afterwards will be quite clear; or without irrigating, if the urine be passed into two glasses, the first portion will be turbid from admixture with the urethral discharge, whilst the second portion remains clear.

When the posterior urethra becomes infected in the acute stages the symptoms are much more severe. Micturition is more painful and greatly increased in frequency, both day and night, the patient often being obliged to pass urine every half-hour. Even after irrigating the anterior urethra the urine passed will be turbid with pus that has accumulated in the prostatic portion or passed backwards into the bladder, and the terminal urine may be tinged with blood. In these circumstances it may be necessary to eliminate *acute prostatitis* or *prostatic abscess*, either of which may complicate an acute posterior urethritis. In either condition, micturition may be very painful, or there may be acute retention; the temperature will be raised, and in cases of abscess there is often a rigor; upon rectal examination the prostate is found much swollen, hot to the touch, and extremely tender, whilst with an abscess a soft fluctuating area may be felt. An acute posterior gonorrhœa is practically always accompanied by infection of the bladder, and the diagnosis between it and cystitis is practically impossible.

Under suitable treatment an acute urethritis may remain confined to the anterior urethra and clear up, but in less favourable cases a slight discharge remains. If this continues for longer than six weeks after the initial onset it is spoken of as *chronic gonorrhœa* or *gleet*. The discharge is small in amount, thin and watery, or may be so slight as only to be present in the morning after a long period of freedom from urination, or as filaments in the urine. There is no pain or increased frequency of micturition, and there is no difference in the subjective symptoms between an anterior and a posterior infection, although in most cases of chronic gonorrhœa both are present.

In any case of chronic urethral discharge examination should be conducted to ascertain not only the seat of infection, but also the nature of the lesion promoting the discharge. The patient should be directed to hold urine for at least three hours before he presents himself for examination, when the anterior urethra may be irrigated thoroughly by a fairly forcible stream of sterile water, the urinary meatus being alternately occluded and opened during the process, so that the whole length of the anterior urethra is distended by the fluid. The washing is then examined for any threads, which, if present, must proceed from the anterior urethra. The patient is then directed to pass urine into two separate glasses: if there is turbidity due to excess of phosphates this is cleared by the addition of acetic acid, when, if any threads or plugs of mucopus are present in the first specimen, they probably arise from the posterior urethra, whereas pus and turbidity of the second show that cystitis is present in addition. If there be any threads in the posterior urethra, or if only a small amount of discharge is present, it is advisable first to fill up the bladder with sterile fluid by direct Janet irrigation, after which the prostate is massaged by a finger in the rectum, and the patient is again directed to pass the fluid from the bladder. Plugs of mucopus will be found if chronic prostatitis is present. In any case the threads from either the anterior or posterior urethra should be spread as a film, stained, and examined under a microscope for pus and micro-organisms.

If the remaining infection is found to be limited to the anterior urethra the latter should be examined under direct vision by the endoscope. A few minims of a 3 per cent solution of cocaine are injected into the urethra and, with aseptic precautions, the largest-sized endoscope tube that the meatus will admit comfortably is passed for about an inch. The canal is then illuminated, and at the same time distended with air by means of the inflating bellows attached to the instrument: each part of the anterior urethra can then be examined successively as the endoscope tube is passed gradually on until the membranous portion of the canal is reached. It will be found much better to examine the urethra in this manner than by first passing the instrument to the full extent and examining the canal as it is withdrawn, for any infection of the urethral glands, infiltration of the walls, or granular areas are observed under aero-distention before the instrument has passed over them. When the whole length has been examined under distention the air is allowed to escape by opening the window of the instrument, and the canal again examined from behind forward by gradually withdrawing the tube, normal urethral walls falling together in a characteristic striated manner, which is altered into a slight rigidity by infiltration, whilst at the same time glandular infection or ulceration is again seen. Similarly, a definite stricture or a small polypus which may keep up a slight urethral discharge can be diagnosed with certainty, and any local treatment for the various lesions applied. By careful examination conducted on these lines we are able to determine, not only which part of the urethra is producing the discharge, but also the nature of the lesion, so that appropriate treatment can be carried out. In most cases in which a gleet remains in spite of treatment with various kinds of injections it will be found that there is an infection of the posterior urethra or prostatic ducts, which no urethral injection except a complete irrigation into the bladder will reach. There is often no abnormality to be detected on digital examination of the prostate per rectum: but after urethral irrigation the secretion squeezed out from the prostate by massage will usually show pus corpuscles in addition to the refractile globules and epithelium which are contained in the normal prostatic secretion. In other cases of obstinate chronic urethritis a distinct infiltrative process will be found in the anterior urethra, a process which results in rigidity of the urethral wall, and in severe cases leads on to stricture. The urethral glands are implicated, and their secretion gives rise to the filaments in the urine, whilst points of pus may be seen to be expressed from their orifices by the pressure of the urethroscopic tube. This infiltration is seen readily by urethroscopy, but it may be imperceptible on the passage of a sound. The urethral meatus is the narrowest part of the canal, and a sound which will completely fill the meatus may still pass steadily through an infiltrated portion of the urethra, even when its normal calibre is diminished considerably.

In spite of all forms of treatment a slight urethral discharge occasionally persists, and the physician may be asked if any infection remains, or whether a patient may be allowed to marry. A chronic urethral discharge may contain gonococci or may be entirely

free from any organisms. Obviously, if any gonococci are found the discharge is still infectious, but there is often difficulty in detecting the organism in these chronic cases, whilst in some they may be found if any slight exacerbation of inflammation occurs. Other cases again show a chronic urethral discharge which resists all treatment, but which contains a few pus and epithelial cells, though no organisms can be found. That pus cells are present in this small urethral discharge is no detriment to marriage, provided that no gonococci can be found, and in practice, if no cocci are found after irritation of the urethra by irritant injections, instrumentation, the free use of alcohol, or in the secretion expressed from the prostate by prostate massage, on several successive examinations, marriage may be permitted.

A urethral discharge may in rare cases be present in *other conditions than that produced by gonorrhoea or septic urethritis*, and as difficulty may arise if one of these cases be met with, it is necessary to mention them.

Herpetic Urethritis.—The mucous lining of the urethra is undoubtedly affected by herpes in the same manner as other mucous membranes, frequently as a tertiary lesion of syphilis. There is irritation of the urethra during micturition, and a slight mucopurulent discharge from the meatus. The small vesicles may be seen by the endoscope, and may be associated with herpes of the prepuce.

Soft Sores in the Urethra are distinctly uncommon. They occur in the terminal portion of the urethra, and cause painful micturition and a profuse, thin, purulent discharge, which contains no gonococci. There may be other sores on the glans penis, and an ulcerated surface will be seen on endoscopic examination. They occur within a few days of infection, and, if extensive, may produce narrowing of the urethra on healing.

Syphilis may affect the urethra either as a hard chancre or as a gumma.

The *chancre* occurs in the anterior end of the urethra, forming a firm indurated mass which can be felt readily on external palpation. The meatus is oedematous and swollen, so that the introduction of an endoscopic tube is impossible: there is a thin, purulent, and often blood-stained discharge from the meatus. A urethral chancre must be diagnosed carefully from peri-urethral infiltration due to urethritis: the period of incubation from the time of infection, the presence of small, hard inguinal glands, the occurrence of secondary lesions of syphilis, and Wassermann's serum test will point to the diagnosis. The *Spirochæta pallida* may be found in the fluid expressed from the surface of the sore.

Gummata of the urethra give rise to a watery urethral discharge when they break down and cause ulceration. They may ulcerate through the canal and form fistulae, but may usually be recognized on careful examination.

Papillomata of the Urethra may occur either in the anterior or posterior portion, as small, pedunculated tumours in the canal, and frequently as a sequel to a chronic gonorrhoea. They may arise, however, in the urethra of a patient who has never had urethritis. They cause a thin, scanty discharge, which does not yield to injections: they are seen readily through the endoscope.

Carcinoma of the urethra is very rare as a primary disease, and in the few cases recorded has been in association with stricture. It forms a tumour in the urethra palpable from the exterior, and causes painful micturition with a blood-stained discharge, and enlargement of the inguinal glands. Suspicion of carcinoma should arise if a hard, irregular tumour be felt in the course of the urethra, without gonorrhoeal infection, in an elderly patient, but the final diagnosis depends on histological examination of a portion of the growth.

Tuberculosis of the Urethra is always secondary to disease elsewhere in the genito-urinary tract, usually of the prostate or seminal vesicles.

Foreign Bodies in the Urethra may cause a purulent urethral discharge if they remain in the canal for any length of time. They may be introduced through the meatus by intent—matches, pins, etc.; or a piece may be detached from a damaged catheter: or a small calculus may come down from the bladder and be arrested. In the latter case the history is usually clear—sudden stoppage of the stream of urine during micturition, with penile pain: a calculus may be felt from the exterior or seen through the endoscope.

R. H. Jocelyn Swan.

DISCHARGE, VAGINAL.—In order to recognize the varieties of pathological vaginal discharges, it is first important to realize what the normal secretions found in the vagina consist of. The secretion normally present must be a mixture of those from the uterine body, cervix, and vaginal wall. That from the uterine body is watery and small in amount, whilst that from the cervix is thick and mucoid, but clear and transparent, like unboiled white of egg. The vaginal secretion is merely a transudation of plasma from the vessels, mixed with desquamated vaginal epithelium, and in virgins looks like unboiled starch mixed with water. Naturally it is small in amount. The bulk of the secretion found in the vagina comes from the cervix, because there are far more glands there than in any other part of the genital tract.

The secretion from Bartholin's gland, which is thin and mucoid, may be copious under sexual excitement, but under normal conditions is scanty, and so does not contribute to the secretions in the vagina. The vaginal mixed secretion is acid in reaction, owing to the presence of lactic acid produced by a long bacillus which is found normally in the vagina. On the other hand, the unmixed uterine secretion is alkaline. Normally, the amount of mixed vaginal secretion should do no more than just moisten the vaginal orifice. When the amount is so great as to moisten the vulva and consequently stain garments, the secretion is pathological.

The composition of an abnormal secretion varies considerably according to the source from which most of it comes. The commonest type is the thick white or yellow discharge associated with inflammatory changes in the cervix. It contains a large proportion of mucus, many leucocytes, masses of shed epithelium from the vagina ('squames'), and bacteria of various kinds. This is quite typical, and is produced by *endocervicitis* and *cervical erosions* of the various kinds. When, however, there is a *corporeal endometritis* present as well, the discharge becomes thinned, white, or yellow, on account of the admixture of much watery secretion from the body of the uterus. The yellow colour is due to the admixture of red blood-corpuscles, and in some cases the fluid may become actually blood-stained. Menorrhagia accompanies these discharges and serves to distinguish a mixed corporeal and cervical endometritis from a simple cervical catarrh. Microscopically the films made from the mixed cases show proportionately less mucus, but otherwise the constituents are the same.

Vaginitis rarely exists alone, but when it does occur the discharge is thick and pasty if it is a simple catarrhal condition—pasty on account of the large admixture of desquamated vaginal squamous epithelium. On the other hand, in granular catarrhal vaginitis the discharge is much more purulent and copious owing to the exudation of more fluid from the exposed blood-capillaries. This is the kind of discharge associated with traumatism of the vagina, especially from the irritation of badly-fitting pessaries, and actual ulceration as in decubitus ulcers on prolapsed portions. Practically no mucus is found in such discharges unless the cervix shares in the inflammatory process.

There is nothing characteristic of *gonorrhoeal discharges* to the naked eye or on simple microscopical examination. The detection of the gonococcus can alone decide the question. This is often a matter of great difficulty, because it is only in the few days immediately after infection that the gonococcus can be found free in the vaginal discharge. In chronic cases the gonococcus must be looked for in three places, in the interior of the cervix, in the urethra and Skene's tubes, which open by the sides of the meatus urinarius, or in discharge squeezed from the orifices of Bartholin's glands. The best plan is to take some discharge from within the cervix, after carefully wiping away discharges from the os uteri with sterile wool, using a Fergusson's speculum. This discharge should be spread on a glass slide and put by to dry. A second film on another slide should then be made, by squeezing the urethra from behind forwards and mopping up any secretion thus made to appear on the meatus, and a third film from the orifices of Bartholin's glands. After drying in the air the films should be fixed by passing through a flame, and then stained by Gram's method, followed by neutral red as a counterstain. In films prepared in this way gonococci are stained red, whilst organisms which retain Gram's stain appear deep violet or black. The gonococci are usually found in the cytoplasm of the polymorphonuclear leucocytes.

Offensive-smelling vaginal discharge is associated with decomposition, and it may be that the discharge itself is decomposing because it cannot escape fast enough from the

passage, or that the source of the discharge is a decomposing substance like a *sloughing fibroid* or *necrotic carcinoma of the cervix*. In the two latter cases the discharge is copious, watery, and blood-stained, with a horribly fetid smell. When the discharge itself is decomposing, it is usually thicker and purulent, and is commonly retained by pessaries or by redundant folds of vaginal mucous membrane. In old women a foul discharge may come from the interior of the uterus, a *pyometra*; in which case pus can be made to flow from the os uteri by squeezing the uterus or passing a sound. It is due to *senile endometritis*, the result of infection, and is often associated with cancer of the cervix or body of the uterus.

Watery blood-stained discharge, not offensive, occurs in *cancer of the body of the uterus*, in early *cancer of the cervix*, with *mucous polypi*, *placental polypi*, and *hydatidiform mole*. The differential diagnosis of these conditions cannot be made from the discharge alone, but must rest upon physical examination combined with the use of the microscope upon materials removed from the uterus.

Vaginal casts may be composed of coagulated surface epithelium, the result of astringent injections or applications, and are easily recognized with the microscope. Membranous flakes may be passed with discharge in cases of *membranous vaginitis*. They consist of vaginal epithelium entangled in coagulated blood-plasma, and present quite a different appearance from casts of coagulated epithelial layers. These membranous masses may be seen lining the whole vagina, and are generally due to special organisms. The diphtheria bacillus (Fig. 608, p. 779) has been found to be the causal agent in such cases, and in one investigated by the writer the *Bacillus coli communis* was the offending organism. T. G. Stevens.

FIG. 192.—Extinct rickets. Age 13. The dwarfism is moderate, and is due to bending and shortening of the thigh and leg bones. There is knock-knee, the tibiae are sabre-shaped, the feet flat. The wrists and ankles are large; the muscles are not affected.

DIZZINESS. (See VERTIGO, p. 911.)

DROPSY. (See EDEMA, p. 511.)

DROP-WRIST.—(See ATROPHY, MUSCULAR, p. 78.)

DWARFISM (Microsomia, Nanosomia). For purposes of diagnosis dwarfism may be divided into two classes, namely: (I) *Dwarfism the result of deformity*; and (II) *Dwarfism without deformity*. Generally speaking, well-proportioned dwarfs owe their defective stature to generalized delay or arrest of development or *infantilism*, whereas deformed dwarfs are stunted in growth only, though the reduction in height may be due rather to the warping or collapse of the bony framework than to actual curtailment of height.

I. DWARFISM THE RESULT OF DEFORMITY.

This kind of dwarfism is due mainly or solely to shortness of legs. In most cases the primary fault lies in (A) the skeleton, but occasionally the dwarfism has its source in (B) deficiency of the brain, and still more rarely is brought about by (C) a local defect of development implicating the lower extremities.

A. **Skeletal Dwarfism** is occasioned by: (1) Rickets; (2) Achondroplasia; (3) Osteogenesis imperfecta; (4) Anosteoplasia; (5) Osteomalacia.

Rickety dwarfism (Fig. 192) is usually moderate in degree, and is due partly to actual shortening of the bones of the lower limbs and partly to bending (bow-legs or knock-knees). It may also be the outcome of anteroposterior or of lateral curvature of the spine. The skull looks big and is of the square or hot-cross-bun type, with bulging forehead; the

shape of the nose is not affected. There is often a pigeon breast or a transverse groove round the lower part of the chest (rickety girdle, Harrison's sulcus), and an hourglass-shaped or, at times, beaked (rostrate) pelvis. The muscles are well developed, and the body is often squat or thick-set.

In *achondroplasia* or *chondrodystrophy* (Fig. 193) the limbs are shorter than in rickets, and the stature is less. The proportions are of the dachshund pattern. The shortening of the limbs is chiefly of the proximal segments, and the body, though actually short, is relatively long. The legs are often bowed, and there may be bending of the upper limb bones. The joints are usually prominent. The forehead is bulging, the bridge of the nose depressed. There is conspicuous lordosis, and the pelvis is small and contracted. The muscles are often disproportionately big, giving the achondroplasia a sturdy appearance and a surprising degree of strength. The fingers are broad, the three middle fingers being of equal length and divergently curved.

Osteogenesis imperfecta (osteopsathyrosis, fragilitas ossium) (Fig. 194) begins in intra-uterine life

or during infancy, and is characterized by brittleness with softening. The bones crumple and then slowly harden. There is not much dwarfing, unless it occurs as the result of the yielding of the bones, and the

muscles are usually weak. The disease is closely related to, and probably sometimes runs on into, osteomalacia.

Aosteoplasia or *cleidocranial dysostosis*. With general impairment of bone growth, causing moderate dwarfism, there is pronounced defect in the formation of the membrane bones. The skull is round and broad, the face small, the dentition delayed; the clavicles are rudimentary or absent. The disease is often hereditary.

In *osteomalacia* the dwarfism is due almost solely to the crumpling of the decalcified bones; but when the disease occurs in childhood there is also some diminution of stature from arrest of bone growth. The muscles are conspicuously weak.

Diagnosis of Skeletal Dwarfism. - In distinguishing rickets from achondroplasia it must be remembered that the most characteristic features of rickety dwarfism are the bending and the post-natal origin, and of achondroplasia the shortness of the limbs (micromelia) and the pre-natal origin. The enlargement of the ends of the bones which is so distinctive of rickets disappears as the disease settles down and the bones continue to grow, whereas in the hyperplastic form of achondroplasia it remains throughout life.

Extreme softening with resulting deformity must cause us to suspect osteogenesis imperfecta or osteomalacia, especially if the bending continues to increase after the age of six years.

Fig. 193. - Achondroplasia. Age 15. The trunk is almost of normal length, and the limbs very short, the proximal being shorter than the distal segments. The metacarpals are enlarged, the forearms and legs curved. The nose is deficient at the bridge. In this case there is infantilism as well as dwarfism.

Fig. 194. - Osteogenesis imperfecta. Age 32. Bending of the tibiae, femora, spine, etc., begun at five years, and continued for nearly ten years before it ceased. There is no epiphyseal enlargement.

Dwarfism may be due solely to *spinal curvature*. If a *kyphosis* it is usually the result of tuberculous disease (caries) of the spine, but is occasionally a local manifestation of rickets (*rhachis*, the spine) or possibly of osteomalacia. When of rickety origin there is not only kyphosis of the dorsal region, but a compensatory lordosis of the dorso-lumbar. If it begins in middle or old age, it is usually osteo-arthritic, but as a rare event it may be due to osteomalacia (*o. senilis*). In the latter event the softening is usually confined to the spine and pelvis, may take place with extraordinary rapidity, and be followed by gradual hardening and fixation in the deformed position.

Scoliosis is usually of mixed origin, the main factor being an inherent laxity of tissue showing itself in weakness of the back muscles and of the spinal ligaments. This laxity is supplemented by faulty positions of standing, sitting, etc., or by the injudicious use of stays. But it is probable that spinal curvature of sufficient severity to produce dwarfism is invariably the result either of rickets or, in rare cases, of a mild and local form of osteomalacia.

B. Cerebral Dwarfism.—This form of microsomia is most pronounced in *microcephaly*, but hydrocephaly, porencephaly, imbecility, or any degenerative cerebral affection of early progressive development may be associated with puny growth. The microcephalic dwarf is characterized not only by the relative smallness of his head (circumference never exceeding 17 in.), but also by his sloping forehead, projecting nose, and receding chin, giving him a ferret- or rat-like physiognomy. He is usually quick of movement

Fig. 195. —Cretinism. Age 20. The infantilism is uniform and extreme. The intelligence, proportions, attitude, manner, correspond with those of a child of 18 months. The features are puffed and disfigured with the characteristic pseudo-œdema.

and restless, and is either imbecile or idiotic, according to the degree of his microcephaly.

C. Dwarfism from Pre-natal Deficiency of the Lower Limbs.—This is of two kinds: *phocomelus* and *ectromelus*. In *phocomelus* the defect is in one or both of the proximal segments, but not of the hands and feet, so that the individual affected resembles a penguin or a seal (*phoca*). In *ectromelus* there is absence of part or whole of the limbs from the feet up.

II. DWARFISM THE RESULT OF DEFECTIVE GENERAL DEVELOPMENT. INFANTILISM.

Well-proportioned dwarfs are not invariably of backward development, for we meet with men of excellent development who, if not actual dwarfs, are so dwarfish in stature that we have to admit the possibility of the existence of a true dwarfism in which there is no infantilism. Nevertheless, generally speaking, the dwarf of correct proportions is affected with infantilism.

To Distinguish Infantilism from Simple Dwarfism.—Dwarfism is a defect of growth, infantilism a defect of development. In determining whether development is implicated, stature, ossification, and sex development are of great but not decisive importance. Thus infantilism may co-exist with gigantism; and the ossification in some patients with symptomatic infantilism is not only not delayed, but is definitely premature. It is also premature in progeria. Moreover,

Fig. 196. Pituitary infantilism.

a sexually mature child of five or six does not cease to be a child because its ossification and sexual condition resemble those of an adult. Evidently therefore neither height, nor sex, nor ossification is a cardinal feature of infantilism. Indeed, in some cases of sexual ateliosis the presence of infantilism is determined by the child-like stature, proportions, and physiognomy alone, the individual being in all other respects a well-developed human being.

The Forms of Infantilism. Infantilism may be widespread among whole races or nations (racial infantilism), or may select certain individuals or families, and occur epidemically or sporadically as morbid infantilism among people of ordinary development. Morbid infantilism is of two sorts, namely: (A) *symptomatic*, the result of causes; and (B) *essential*, or cryptogenetic.

1. Symptomatic Infantilism.

This is seldom or never of extreme degree, has no uniform type of physiognomy, and, being an acquired condition, is never transmitted. It is best classified according to the nature of the cause by which it is produced.

It may be the result of *intoxication* with lead, syphilis, wine, tobacco, or with the poison of rheumatic, scarlet, or other fever. Herter claims that the intoxication may arise from over-abundance of the normal flora of the intestine (intestinal infantilism).

It may be the result of *correlation*, as when it is associated with *kyphosis* or with *splenomegaly*, or with *hypertrophic cirrhosis* of the liver. Perhaps the best example of this form of infantilism is that which is associated with *microcephaly*. In some microcephalic dwarfs there is not only an impairment of growth, constituting dwarfism, but the development of the whole body is stayed, apparently because it is the custom for a certain development of the body to go with a certain size of the brain, and such customs are liable to be maintained even under abnormal conditions. Dwarfs with diminutive heads may be of just proportions and of fairly good intelligence, provided the growth of the body is so retarded that it

Fig. 197.—(a) celiac infantilism. On the right is a girl, age 15 1/2, with celiac infantilism, standing beside a normal girl, age 14 years. Though the celiac disease has long been extinct, the development is still seriously retarded. Puberty set in eighteen months after this photograph was taken, and development then became mature, but growth remained permanently stunted (dwarfism).

Fig. 198.—Mongolism. Age 14. The general development is delayed. The physiognomy is undeveloped and slightly mongoloid. The head is brachycephalic, the occipital region flat. The boy is an amiable imbecile.

these cases of 'myxœdème fruste', but the term should only be applied when the intelligence is defective and uniform improvement. The thyroid inadequacy may, however, not be primary, but a mere incident in some other form of infantilism, e.g., ateliosis.

remains in keeping with the growth of the brain. In *thymic* infantilism there is fatness with anæmia, and liability to syncopal attacks, which often end in death.

It may be due to the *deficiency of a hormone* which ordinarily stimulates development. There are two forms: (a) *Thyroid*; and (b) *Pituitary*.

Thyroid infantilism in its most characteristic form *cretinism* (Fig. 195) is unmistakable; but cases of infantilism occur in which the physiognomy, stunting of growth, and backward sex development suggest mere thyroid inadequacy. Some reserve the name thyroid infantilism for

sets in as a result of giving thyroid extract. It may be primary, but a mere incident in some

In *pituitary infantilism* (Fröhlisch's syndrome, *Fig. 196*) there is fatness, chiefly of the abdomen, buttocks, and proximal segments of the limbs, with conspicuous genital backwardness. Polyuria or glycosuria is often present, and there may be drowsiness or nutritional changes in the skin and its appendages. Sickness, headache, or other symptoms of a cerebral tumour are occasionally present.

Fig. 199. — Anangioplastie infantilism. Age 16. There is general delay of development, but not to an extreme degree. The physiognomy and proportions are of the adult pattern, but sex development is more immature.

In *cardiac infantilism* (*Fig. 197*) the retarded development is the result of cardiac disease (see p. 216). In course of time development is resumed, but often the growth of the body remains permanently dwarfed. This is probably the commonest form of infantilism, and the same as Herter's *intestinal infantilism*.

Mongolism (*Fig. 198*) is distinguished from cretinism or myxedème fruste by the predominance of the imbecility as compared with the slightness of other cretinoid symptoms. In reality the physiognomy is only cretinoid because it remains of the infantile type. It is not disfigured by the thick lips and general pseudo-ardema of cretinism, and the tongue, though sometimes protruding, is not large. The eyes remind one of the obliquely-set eyes of the Chinaman, but it is sometimes difficult to make out the resemblance. The ligaments are lax, and mongols are liable to become knock-kneed and to have 'double-jointed' thumbs. There is often some valvular affection of the heart.

In a given case of infantilism it may be impossible to decide how much is due to correlation, how much to intoxication, how much to hormonal deficiency, and how much to mere lack of nutrition. This may be said, for example, of cardiac, of arterial,

of renal, and of pancreatic infantilism.

Cardiac infantilism exists when there is some dominating incapacity of the cardiac valves. Sometimes there seems to be defective development of the whole arterial system, constituting *anangioplastie infantilism* (*Fig. 199*).

Renal infantilism is consecutive to chronic Bright's disease, and is suggested when there is polyuria, albuminuria, or other symptom of Bright's disease, and no indication of a prior syphilitic or other intoxication. The symptoms which give rise to *pancreatic infantilism* are so like those of cardiac disease that there is as yet no certain way of distinguishing between them.

B. Essential or Cryptogenetic Infantilism.

This is distinguished from symptomatic infantilism by its pronounced degree, by its seemingly spontaneous appearance, and by its occasional heredity. There are two forms: (1) *Ateliosis*; and (2) *Progeria*.

Ateliosis (*Fig. 200*) is primary, spontaneous infantilism. It may begin at any age of progressive development, and its characters are for the most part those normal to the age of its first appearance. It usually begins in infancy or early childhood, and perpetuates the

Fig. 200. Essential infantilism (achrosia). An ateliotic boy, age 12, standing beside his normal and taller brother, age 6 years. The size, facial features, and bodily proportions are those of a child of 4. The sex organs are still more backward. The intelligence is unusually good, but of simple, childish type.

size, proportions, and physiognomy of this time of life. It is prone to be associated with cryptorchism, or with some corresponding ill-development of the ovaries, causing divergence into two varieties, sexual and asexual. In *asexual ateliosis* the physical and mental features of infantile life are stereotyped; but in *sexual ateliosis*, though the physiognomy and proportions remain infantile or childish, the onset of puberty (often greatly delayed) brings with it some accession of growth and the addition of the primary and secondary sex characters of the adult.

Progeria (Fig. 201) is primary, spontaneous infantilism mingled with premature senility (senilism). Hence, with shortness of stature and other indications of infantilism, there are baldness, emaciation, arterial sclerosis, and general decrepitude. Death from angina pectoris or other senile disease may ensue at 18 or even earlier. It is very variable in its manifestations. There may be no emaciation, and life may continue until 30 or longer.

Hastings Gilford.

DYSARTHRIA. (See SPEECH, ABNORMALITIES OF, p. 769.)

DYSCHEZIA. (See CONSTIPATION, p. 158.)

DYSIDROSIS. (See SWEATING, ABNORMALITIES OF, p. 803.)

DYSMENORRHOEA owes its origin to a variety of causes, which must be differentiated carefully in order that treatment may be successful. The following table presents the causes of the three common varieties:

1. SPASMODIC.	2. CONGESTIVE.
Congenital malformations	Endometritis
Deficient uterine muscle	Uterine congestion
Long conical cervix	Retroversion and flexion
Stenosed external or internal os	Uterine fibroids
Neurasthenia.	Salpingo-oöphoritis
	Pelvic peritonitis
	Small cystic ovary
	Hæmorrhagic ovarian cyst
	Neurasthenia.
3. MEMBRANOUS.	

The distribution of the cases into these three classes is often easy: in the first place, because spasmodic cases are practically always *primary*, that is, they commence with the onset of menstruation; whilst congestive and membranous cases are *secondary*, that is, acquired as a result of some definite lesion. Further, the nature of the pain is often characteristic of the type of case, for in spasmodic cases the pain begins with the flow or only just before it, is aching in character, often with griping or colicky exacerbations. In the congestive cases, on the other hand, the pain is continuous and aching, and begins some hours or days before the flow. In typical cases also this pain is relieved by the flow. In the membranous cases the nature of the pain partakes of the characters of both the former types, being aching and continuous first, then becoming colicky and spasmodic when the uterus is attempting to expel the characteristic membrane or cast, and being finally relieved when this comes away. Many cases are met with in which the pain partakes of the nature of both the congestive and spasmodic types. This usually means that a woman who originally had spasmodic dysmenorrhœa acquires some lesion which in its turn gives rise also to the congestive type of pain.

Having settled that a case belongs to one of the three main types, it is not very difficult to work out the actual causation. This is more difficult in the spasmodic cases than in the congestive, because the latter depend upon well-defined lesions, and the former do not.

1. Spasmodic Cases. The causation of the pain in this type of case is obscure, but

Fig. 201. — Progeria. Age 15. The stature and proportions are childish, but the physiognomy, leanness, and baldness are elderly. The scalp was in reality sparsely covered with grey hair. The ear lobule is absent, the nasal cartilages are conspicuous, and the fingers bulge out owing to the prominence of the epiphyses.

is now believed to be the result of tissue tension in the endometrium, from the extreme congestion which occurs in it just before the flow begins and during the first few hours of the flow. It is often associated with a congenital malformation of the uterus, which can be discovered on bimanual examination. The uterus may be small, but of the adult type: it often has an exaggerated anterior bend, the 'cochleate' uterus of Pozzi: and, in addition, the vaginal portion of the cervix is often too long, with a conical shape, and a very small pin-hole external os. Into such uteri the sound may pass with difficulty, owing to stenosis and rigidity of the internal os. It is more than likely that imperfect development of the uterine muscle has a share in the causation of pain, especially in those cases in which griping or colicky exacerbations occur. The muscle being imperfect, it is also possible that the endometrium is abnormal in these cases, unduly fibrous perhaps, and resistant—a point which our present knowledge does not prove or disprove. One proof, however, of the truth of these views is the effect of pregnancy and labour on such cases. They are nearly always cured, owing to the great muscular development during pregnancy, and the extreme stretching of the lower segment during labour. Neurasthenia also colours and increases the pain in these cases: but, by itself, will not start a spasmodic any more than a congestive dysmenorrhœa.

2. Congestive Cases. It is unnecessary to differentiate the congestive cases as tubal, ovarian, or uterine, because the underlying cause in all is uterine congestion accompanying such lesions as are shown in the table. The differential diagnosis of these lesions is to be made by a careful consideration of the history, combined with bimanual examination of the pelvic organs, and, if necessary, curettage of the uterus, which also serves to cure the cases of pure endometritis. Cases due to *endometritis* are to be recognized by the cardinal symptoms of this lesion, namely, menorrhagia, leucorrhœa, often blood-stained, and chronic backache. These symptoms accompany slight enlargement of the uterus without any irregularity in shape such as would occur if fibroids were present. Simple *retroversion and flexion* can be recognized on bimanual examination: the fundus will be felt posteriorly, the cervix looking directly down the vagina in a forward direction. *Salpingo-oophoritis* in its typical chronic form gives rise to irregular very tender swellings on either side and behind the uterus, sometimes forming definitely retort-shaped swellings, especially if pus is present in the tubes. Fixation of these swellings and of the uterus is a very definite sign of the disease: whilst the history of one or more attacks of acute illness, with pelvic pain, will assist to make the diagnosis certain. The *small cystic ovary* may exist without obvious salpingo-oöphoritis, and without widespread fixation. The ovary is found to be permanently enlarged and irregular in shape from the projection of cysts from its surface. Small hæmorrhagic cysts of the ovary, the contents of which may be 'tarry' or of chocolate-like consistence, have recently been drawn attention to as important causes of dysmenorrhœa. They are always fixed, and are now believed to be often of endometrial origin (*adenomyoma of the ovary*). *Neurasthenia* is included under this heading because any menstrual pain is made worse by it, and only a very slight lesion need be present for this nerve weakness to accentuate any pain arising from it.

3. Membranous Cases.—The membrane, or cast, is of two types, and is easily recognized and distinguished from other uterine casts, such as those formed by the decidua of pregnancy. The classical cast of membranous dysmenorrhœa is hollow, triangular, not more than one-eighth of an inch thick, and possesses three openings. This, however, is not the common form: for in most cases the cast is solid, and formed by the mucosa being rolled upon itself. These casts contain endometrial stroma and glands crowded with leucocytes. The solid cast may be nearly half an inch thick, and look microscopically as if it were composed of endometrium into which hæmorrhage and leucocytic infiltration had occurred. The glands in it are broken up, and often lie on the outside. These casts never contain any compact masses of large cells of the decidual type, but an occasional hypertrophied cell may be found. Decidual casts, on the other hand, are the result of pregnancy, and consist of compact masses of large polygonal cells without any fibrillated connective tissue. They contain glands with hypertrophied epithelial linings, and often show large hæmorrhagic foci. The occasional presence in them of chorionic villi absolutely settles the diagnosis.

It must not be forgotten that cases of dysmenorrhœa may be confused with those of abdominal pain due to other lesions unconnected with menstruation; and the

differentiation of such cases may be a matter of considerable importance. It is conceivable that the following conditions may be mistaken for dysmenorrhœa :—

Appendicitis	Torsion of an ovarian cyst pedicle
Colic, intestinal, renal, or hepatic	Hæmorrhage from or into a Graafian follicle
Perforated gastric ulcer	Rupture of an ovarian cyst or pyosalpinx
Ruptured tubal gestation	Dyspepsia with flatulent distention.

Obviously, some of these lesions are dangerous to life, and therefore it is essential that they be not overlooked. The danger of this occurring is increased if any of these lesions start at or near the expected time of a menstrual period, and would hardly arise at all if a menstrual period had taken place recently, or was not expected for some days. It will be noted that all these lesions are accompanied by sudden abdominal pain, which might perhaps lead to a suspicion of spasmodic dysmenorrhœa, but hardly of congestive, owing to the character of the pain.

T. G. Stevens.

DYSPAREUNIA, or painful coitus, may depend on a variety of local lesions which require careful differentiation for their appropriate treatment, or it may exist when no local lesion can be found at all. It is associated closely with vaginismus, or painful spasm of the levator ani muscle on attempts at coitus, and the same lesions which cause simple dyspareunia may also give rise to vaginismus. It is remarkable that in some women a small local lesion will produce no pain upon attempts at coitus which in others will cause pain accompanied by violent spasm of the levator ani. In some cases pain arises because there is a difficulty of penetration of the vaginal orifice, whilst in others there is no difficulty, but pain is caused. The lesions which commonly give rise to dyspareunia are the following :

Congenital absence of the lower part of the vagina	Kraurosis vulvæ	Prolapsed tender ovaries with retroverted uterus
Unruptured hymen	Neuritis of the pudic nerve	Salpingo-oöphoritis with adhesions
Inflamed hymeneal orifice	Healed perineal lacerations	Anal fissure
Vulvitis	Urethral caruncle	Thrombosed and inflamed piles.
Bartholinitis	Urethritis	
Leukoplakic vulvitis	Cystitis	

It will be noted from a perusal of the above that the lesions fall into natural groups, according as the situation of the lesion is at the vulva, the uterus and ovaries, the urinary passages, or at the anus and rectum. Consequently it is necessary to carry out a detailed examination of any case of dyspareunia in order to find out whether any of these well-defined lesions are present.

The commonest lesion is certainly *inflamed hymeneal remains*, very often gonorrhœal in origin and accompanied by redness and swelling of the orifice of the duct of Bartholin's gland. The lesion is self-evident on inspection, and the parts are acutely sensitive to the least touch. *Leukoplakic vulvitis* is a lesion that is obvious from the white, sodden appearance of the labia minora, and causes pain on account of the sensitive cracks and fissures which accompany it. *Kraurosis vulvæ* causes actual contraction of the vaginal orifice, and consequently penetration is difficult and causes pain. The red projecting growth from the meatus urinarius, *caruncle*, is self-evident and acutely tender, whilst *urethritis* is diagnosed by the issue of pus on squeezing the urethra. *Cystitis* is diagnosed by the presence of pus and mucus in the urine, accompanied by frequency of micturition, and it causes pain because the bladder is painful in such cases and intolerant of the disturbance caused by coitus. *Pudic neuritis* is not a well-defined condition, but can be recognized by tenderness along the pudic nerve just inside the vaginal orifice, where the nerve passes along the inner side of the ischial ramus. In *prolapsed tender ovaries* and *backward displacements* there is no pain on penetration and no difficulty, but coitus gives acute pain. The condition is recognized by a bimanual examination, the same remarks applying to *salpingo-oöphoritis*, bearing in mind that there is usually a history of some acute attack of pelvic peritonitis in such cases. *Anal fissure, thrombosed and inflamed piles*, can be recognized only by a careful examination of the anus and rectum by the finger and speculum.

In the cases which occur without local lesions the vaginal entrance will be found to be hyperæsthetic as a rule, and penetration is impossible. Such cases are almost always

accompanied by spasmodic vaginismus. The most careful examination fails to demonstrate a lesion in these cases, and they are usually termed 'neurotic' for the want of a better term. Cases of this sort do not necessarily mean absence of sexual desire; on the contrary, many such patients are desirous of the consummation of marriage. Enlarging the orifice, or even child-bearing, does not cure a true case of this nature; it must be in some way a disorder of function of the nerve centres. These cases must be distinguished from those in which the underlying factor is absence of sexual desire and actual dislike of the sexual act. Unhappy and unsuitable marriages conduce to this state of affairs, and the patient is liable to complain of pain when dislike is really what is meant. There is no difficulty in penetration in such cases.

T. G. Stevens.

DYSPEPSIA. (See FLATULENCE, p. 302; HEARTBURN, p. 376; and INDIGESTION, p. 395.)

DYS-PHAGIA literally means difficulty in swallowing, but the term itself does not indicate whether the difficulty is mechanical, nervous, or due to pain; there are consequently several entirely different groups of cases, to each of which the term dysphagia has been applied:

1. **Dysphagia due to Mechanical Obstruction to the Œsophagus.** The usual history of progressive mechanical obstruction to the œsophagus is as follows: There is little or no pain, but the patient notices that whereas formerly he could swallow anything with ease, he is beginning to experience difficulty with the more solid kinds of food, such as meat, dry bread, and vegetables, so that he is obliged to live mainly upon pulpy foods, milk puddings, gruel, and the like. Later he can swallow only liquids; ultimately he finds that even these are apt to be regurgitated soon after they have been swallowed, and there is often a sense of obstruction at some point between the level of the cricoid cartilage and the lower end of the gladiolus, which latter corresponds, as regards sensation, with the cardiac end of the œsophagus. When with the above history the patient gives a definite account of having, at some former date, swallowed some strong irritant or corrosive substance, such as an alkali or a mineral acid, the diagnosis of *fibrous stricture* from *corrosive* injury is probable. When similar obstruction succeeds the swallowing of a *foreign body*, such as a tooth-plate (*Fig. 202*), a large piece of bone, or a coin, the diagnosis is also easy as a rule, though in some cases there may be doubt as to the existence of a foreign body in the œsophagus unless the œsophagoscope is used, or the X rays employed with or without bismuth (*Fig. 203*). Where the symptoms are not

Fig. 202. Tooth-plate impacted in the larynx, causing sudden death from acute dyspnoea and asphyxia.

directly attributable to anything of this nature, however, but come on insidiously, the diagnosis generally lies between *squamous-celled carcinoma* of the œsophagus, *carcinoma of the stomach* directly invading the lower end of the œsophagus, and *aortic aneurysm* stenosing the œsophagus from outside. There is danger in passing a bougie until aortic aneurysm has been excluded, a matter which is often difficult when clinical grounds alone must be relied on; for the aneurysm most liable to stenose the œsophagus is one affecting the descending thoracic aorta, behind the heart, where it can be neither heard nor felt, and it is placed too far along the aorta to cause inequality of the pulses, inequality of the pupils (from interference with the cervical sympathetic), paralysis of a vocal cord (from interference with the left recurrent laryngeal nerve), tracheal tugging, or pain down either

arm. The only other effects besides œsophageal obstruction likely to be due to aneurysm in this position are : pain in the dorsal region of the spine, possibly radiating along the course of one or more of the mid-dorsal intercostal nerves towards the left and simulating intercostal neuralgia ; and perhaps obstruction to the lower part of the root of the

Fig. 203. An aneurysm blocks the œsophagus, it does not show, but is behind the bismuth food, the lower border of which has crossed the heart. As a result of the X-ray examination the aneurysm was further explored and the patient died, pneumonia, *vide Fig. 205.* Descending aorta.

between primary growth of the œsophagus and infiltration of the œsophagus by a growth starting at the cardiac end of the stomach is often one of great difficulty, unless there have been definite gastric symptoms before dysphagia set in. Secondary nodules would naturally be looked for, especially in the liver or in the lymphatic glands in the lower part of the neck. A history of syphilis and evidence of syphilitic aortic regurgitation, especially in a man between the ages of forty and fifty who had been a hard manual worker and not teetotal, would render aneurysm probable.

When aortic aneurysm can be excluded, much information as to the nature of an œsophageal obstruction may sometimes be obtained by the use of an œsophagoscope, and the latter can be used at the same time in facilitating the removal of such things as a foreign body or lump of food that may have become impacted in the craters of an ulcerating stricture.

Dysphagia lusoria is a very rare condition due to compression of the œsophagus by the right subclavian artery when it arises from the aorta beyond the left subclavian and passes to the right side either in front of or behind the œsophagus ; the diagnosis in such cases is difficult unless it be guessed at on account of the co-existence of other congenital deformities such as transposition of the viscera or *morbus cordis*.

left lung, causing impairment of note, of air-entry, or of voice sounds, with or without some crackling râles over the left lower lobe behind. X-ray examination is essential ; if the aneurysm cannot be seen in an antero-posterior view of the chest (see *Fig. 214*), owing to the heart shadow lying in front of it, it may become obvious in the left oblique position, which is the best for viewing opacities in the posterior mediastinum. The site of the obstruction may be demonstrated with the X rays after the patient has swallowed a capsule or gruel containing bismuth or barium chloride (*Figs. 204, 205*). The older the patient, the more likely is the obstruction to be due to carcinoma of the œsophagus and not to aneurysm. The differential diagnosis

Fig. 204. Skiaenam, after a bismuth meal, showing the bismuth held up by a malignant stricture of the œsophagus at about the level of the bifurcation of the trachea.

Esophageal pouches cause symptoms which can seldom be interpreted with certainty unless the case is watched for some time. Generally the patient can swallow with

Fig. 205.—Skigram taken in the semi lateral position after bismuth administration in a case of stenosis of the esophagus by a carcinoma at the cardiac orifice. The diagnosis was verified at subsequent operation. The bismuth had been taken 20 minutes previous to the X-ray examination and none had yet entered the stomach. (Fig. Dr. C. Thurstan Holland.)

ease on some days, but with considerable difficulty on others: aneurysm, new growth, and traumatic or corrosive obstruction will be excluded partly by the results of X-ray examination and partly by the age—pouch cases are relatively young. The point which suggests the diagnosis of a pouch is that the patient who has been able to swallow perfectly well for a few days, and then begins to have difficulty in getting the food down, finds relief presently on the regurgitation—clearly not from the stomach, but from some situation higher up—of a larger quantity of food material than had been swallowed immediately before, including perhaps articles which were taken one or more days previously. The reason for these symptoms is that the pouch does not obstruct the esophagus until it becomes very much distended by the gradual accumulation in it of portions of the food swallowed, relief coming when the greatly distended sac empties itself back into the esophagus (Fig. 206).

2. Dysphagia due to Nervous Causes without Obstruction.

The two commonest varieties of dysphagia due to purely nervous causes are probably *post-diphtheritic* and *hysterical*. The former is characterized by regurgitation of the food through the nose due to paralysis of the soft palate; inspection may demonstrate the flaccid condition of the latter; there may have been a history of sore throat,

of other cases of diphtheria in the patient's neighbourhood, or Klebs-Löffler bacilli may have been found, or may still be found, in the patient's throat. When regurgitation of the food through the nose develops in a person who is not known to have had diphtheria, the symptom will arouse suspicion that diphtheria of a mild type has occurred but has been overlooked. There may or may not be other signs of peripheral neuritis, or there may be paralysis of the ciliary muscles of the eyes.

Hysteria as a cause for dysphagia is familiar enough under the heading of *globus hystericus*, the diagnosis of which is not as a rule difficult, especially if the patient be a young woman who has suffered from other functional nervous affections, for instance hysterical aphonia.

Less common varieties of dysphagia of nervous origin are:—

Bulbar paralysis, in which the characteristic and progressive disability in the use of the lips, tongue, pharynx, and larynx points at once to the diagnosis, the only difficulty that may arise being perhaps in distinguishing true bulbar paralysis, in which the lesion is in the motor nuclei of the medulla oblongata, from pseudobulbar paralysis, where the lesion is due to bilateral cortical softening: in the

Fig. 206.—Skigram of residual bismuth in a simple pouch of the esophagus which caused dysphagia. The lateral boundaries of the pouch are indicated by the arrows. (Fig. Dr. W. H. Caldwell.)

true form there is atrophy of the tongue, in the pseudo variety the tongue does not atrophy, and chiefly upon this point is the differential diagnosis made.

Syphilitic degeneration of the medullary centres may produce symptoms not unlike those of ordinary bulbar paralysis, but it is generally differentiated by the fact that other cranial nerves, particularly those of the eyeball, are probably affected at the same time, and there may also be evidence or a clear history of syphilis, with or without a positive Wassermann's reaction in the blood or cerebrospinal fluid, together with excess of lymphocytes in the latter.

Lead poisoning and *alcoholism* may also be responsible for degenerative lesions which affect the nerves concerned in the process of swallowing.

General paralysis of the insane ultimately results in inability to swallow; the swallowing reflex is amongst the very last to disappear, and the diagnosis has been established long since upon other grounds.

Spasmodic dysphagia, due to spasm of the muscular coats of the œsophagus and pharynx, is probably the cause of globus hystericus, but similar spasticity may prevent swallowing in much more serious diseases, and constitutes a prominent symptom in *hydrophobia*, in which any effort to swallow liquids produces the symptom in extreme degree. The history of a dog-bite as a source of contagion is the chief point in arriving at the diagnosis. The symptoms of *acute encephalitis lethargica* are protean, on account of the very variable distribution of the exudative lesions in the brain, mid-brain, cerebellum, pons, and medulla: in most cases dysphagia is not pronounced, but in some, apparently when the medullary centres in particular are picked out, acute dysphagia may precede coma, and, the patient being in a state of active delirium at the same time, the disease may then simulate hydrophobia very closely, and the diagnosis may be in great doubt until the clinical course of the condition has been watched.

Botulism—poisoning by the *Bacillus botulinus*—is uncommon, but small epidemics of it occur from time to time, and dysphagia is an early and pronounced symptom. The infection is generally due to preserved foods which may seem to have been quite sweet at the time of eating them. Potted meats have been to blame sometimes; more often, home-bottled fruits or vegetables which have not been recooked after the bottle has been opened. In a fairly typical case there is a latent period of from six to twenty-four hours; the patient then feels nauseated, vomits, and on trying to swallow has difficulty in getting even water down; the tongue feels stiff, the muscles of deglutition will not work properly; the voice becomes husky and weakens until there is complete aphonia with aphagia; the temperature is often subnormal, the pulse-rate raised; the eyes are affected by asymmetrical ptosis or strabismus; vomiting may persist and become associated with headache and abdominal cramps; drowsiness supervenes, deepens into coma, and the patient dies of respiratory failure within a very few days of the onset of the illness. Others who have partaken of the same food have been ill in a similar way, and this gives the clue to the diagnosis; if any of the tainted food happens to have been thrown out to the poultry, the latter die of acute paralysis in a similar way. To recover the organism from the food or from the hens needs special bacteriological knowledge, for the *Bacillus botulinus* requires anaerobic methods for its culture.

Myasthenia gravis is a characteristic disease, in which the affected muscles are perfectly able to do their work when they first begin, but become fatigued with such rapidity that successive contractions become less and less effectual, until they cease, and the affected muscles can only work again when they have been given a rest. The neck muscles, and those of the eye, larynx, and mouth, become involved early (*Fig. 245*, p. 291), and difficulty in swallowing after the first few mouthfuls is sometimes a characteristic feature of the case. The myasthenic electrical reaction (see REACTION OF DEGENERATION, p. 724) serves to distinguish these cases from those due to bulbar paralysis.

Then there are those curious cases of uncertain pathology in which the œsophagus becomes enormously hypertrophied and dilated, and at times the patient cannot swallow, though a bougie passes perfectly well—*cardiospasm*, *achalasia of the cardia*, or *idiopathic dilatation and hypertrophy* of the œsophagus. Some regard the condition as due to cardiospasm—an erroneous spasmodic contraction of the cardiac orifice which refuses to relax for the ingress of food into the stomach; a more recent view is that the trouble results, not from undue or excessive spasm, but from defective relaxation of the normal tonic—

a condition to which the term *achalasia* has been applied; others, again, believe that the mischief is due in the first place to a prolapse of the lower end of the œsophagus into the cardiac end of the stomach, the pouting prolapsed mucosa becoming nipped by the cardia and thus producing the variable obstruction. Whatever the pathology, the œsophagus becomes more and more dilated and hypertrophied from the cardia upwards. The symptoms may have extended over years, and the diagnosis may have been one of chronic indigestion with recurrent bouts of vomiting, until the real nature of the trouble is demonstrated by the use of bismuth or barium and the X rays (*Figs. 207, 208*).

3. Dysphagia due to Mechanical Defects of the Mouth or Pharynx, the Œsophagus being Normal.

—This group of cases includes patients suffering from such conditions as widely cleft palate, syphilitic stenosis of the pharynx, inability to use the tongue, either because it is acutely swollen from glossitis, bee-sting, or angina Ludovici, or because it is fixed from carcinomatous infiltration, and so forth. There is little need to enter into the differential diagnosis of this variety of dysphagia, for it can generally be determined by direct examination of the buccal cavity. Mumps, quinsy, tuberculous caries of the cervical spine, and post-pharyngeal abscess belong to the same group, the last-named causing more dyspnoea than dysphagia, and being confined to quite early childhood.

Fig. 208.—Skiagram in the semi-lateral position after administration of bismuth in a man, age 46, suffering from 'cardiospasm' or idiopathic dilatation of the œsophagus. History of 28 years' vomiting, indigestion, pain after food. Had been to many physicians; had taken "all the medicines in the pharmacopœia", but was never diagnosed correctly until bismuth and X-ray examination was resorted to previous to a proposed gastro-enterostomy. (By Dr. C. Thorstein Holland.)

Fig. 207.—Skiagram of the lower end of the œsophagus after the administration of a barium meal in a case of achalasia cardia. Showing the marked dilatation of the œsophagus, and the characteristic triangular projection of its lower end into the stomach. (By Dr. Lindsay Lock.)

4. Dysphagia in which there is no Mechanical Obstruction, but in which the Act of Swallowing causes the Patient so much Pain that he hesitates to Swallow.

The chief causes of dysphagia which come under this heading are: Inflammatory affections of the mouth or tongue, including the different varieties of *stomatitis* (p. 661); *pemphigus* or *erythema bullosum* of the buccal cavity, evidenced by similar eruption upon the skin (see BULLÆ, p. 123); *ulcers of the tongue*, whether malignant, gummatous, tuberculous, actinomycotic, leprosy, or due merely to erosion by a carious tooth or an ill-fitting tooth-plate; *sore throats* of various kinds (see SORE THROAT, p. 757); pain in the mouth, pharynx, or œsophagus after swallowing acute irritants or fluids that are either exceedingly cold or burning hot; and *inflammatory affections of the larynx* and its immediate neighbourhood.

The nature of the buccal lesions will generally be indicated by inspection followed by bacteriological or other special tests.

The chief difficulties arise when the cause of the dysphagia is a painful affection of the larynx. Rarities such as variolous,

lupoid, leprous, typhoidal, decubital, and traumatic ulcers of the larynx will seldom be diagnosed unless there is obvious collateral evidence, such as the eruption of small-pox upon the skin, residence in leprous countries, prolonged confinement to bed, and so forth, to indicate the nature of the case. The commoner varieties of laryngeal trouble which produce dysphagia are *acute laryngitis*, *tuberculous laryngitis* with or without ulcers, *carcinomatous ulceration* of the larynx, and *syphilis*. Laryngoscopic examination is essential, local anaesthesia by the use of cocaine generally being necessary first. If tubercle bacilli

can be found in the sputum, or if there are abnormal signs at the apices of the lungs, the diagnosis of tuberculous laryngitis is probable, and the pallid swelling of the aryteno-epiglottidean folds, and, still more so, multiple small ulcers of the edge or posterior surface of the epiglottis or of the free edges of the true or false vocal cords, or similar ulcers in other parts of the larynx, bilaterally situated, would indicate the diagnosis with certainty (*Figs. 209, 210*): the chief difficulty arises in the more chronic cases in which, after the larynx has become involved, the lung condition has improved, and tubercle bacilli may not be

Fig. 209.—Tuberculous ulceration of the epiglottis and one aryteno-epiglottidean fold.

Fig. 210.—Tuberculous of the larynx; the mouse nibbled appearance of both vocal cords is typical.

Fig. 211.—Early epithelioma of one vocal cord. (*Figs. 209-211 kindly lent by Sir St Clair Thomson.*)

Fig. 212.—Papilloma on an inflamed vocal cord. This occurred in a patient over 60, and aroused suspicion of a possibility of malignancy, but the cord remained mobile, and the growth had not increased markedly when it was removed—three years after first coming under observation. (*From Sir St Clair Thomson's "Fractures of the Nose and Throat" (Glasgow), by kind permission of the author.*)

found in the sputum. Epitheliomatous ulceration of the larynx may be very extensive and yet for a long time remain confined to one side (*Fig. 211*); this unilateral distribution of the infiltration is often important in distinguishing epithelioma from syphilis of the larynx, whilst the latter may also be distinguished by the repair which may ensue even after extensive destruction of the tissues has led to much deformity of the parts. The influence of salvarsan or potassium iodide and mercury upon the lesions may assist the diagnosis, and Wassermann's serum test may be employed. Doubt may remain, however, and

sometimes, where it is very important to arrive at a certain diagnosis as soon as possible, a small portion of the affected tissue may be excised and examined microscopically. A papilloma of a vocal cord may have to be diagnosed from a malignant tumour (*Fig. 212*). When tuberculosis, syphilis, and new growth are excluded, and yet laryngitis is present, the probability is that it is due to some infecting organism. Probably the symptoms will have started more or less acutely, even though they persist and become chronic: laryngeal inspection may show acute hyperaemia and injection of the parts, with extensive oedema, without ulceration, and the nature of the micro-organism concerned—the diphtheria bacillus, streptococcus, pneumococcus, etc.—may be determined bacteriologically by preparing cultures from local swabbings. It is possible, of course, for two or more maladies

to occur simultaneously, and it is particularly difficult to distinguish syphilitic laryngitis from tuberculous in a syphilitic patient who has undoubted phthisis; similarly, it may be difficult to distinguish catarrhal laryngitis from tuberculous in phthisical patients, and so on; indeed, in many instances the diagnosis may be one of opinion only. *Measles* is very apt to be accompanied by laryngitis, which may often be merely catarrhal, but which not infrequently is due to diphtheria developing synchronously with the measles. In order to exclude diphtheria, it is always advisable to take swabbings for bacteriological investigation even where it seems almost obvious that the laryngeal catarrh is merely part of the general coryza of measles. In all these cases dysphagia will be accompanied by hoarseness or other alteration in the voice pointing to an affection of the larynx.

Herbert French.

DYSPNŒA, or difficulty or distress in breathing, may be of almost any degree, from simple shortness of breath on relatively strenuous exertion, to the panting, persistent, orthopnoea of mitral stenosis in its latest stages. Many conditions, moreover, may produce no more than mild dyspnœa at one time and yet be capable of causing extreme and distressful dyspnœa at another, so that it is not easy to separate one cause from another on the basis of the mildness or the severity of the symptom. The following is a tabular subdivision of its main causes:—

Failure of the Right Side of the Heart:—

Secondary to valvular disease:

Mitral stenosis	Mitral stenosis and regurgita-	Aortic disease with secondary
Mitral regurgitation	tion	mitral regurgitation
		Congenital heart disease.

Secondary to affections of the heart muscle:

Fatty heart	Adherent pericardium	Primary alcoholic heart
Fibroid heart	Pericarditis	Atheroma of the coronary arteries.

Secondary to high systemic blood-pressure:

Arteriosclerosis	Hyperpiesis	Polycythæmia	Granular kidney.
------------------	-------------	--------------	------------------

Secondary to affections of the lung or pleura:

Emphysema	Chronic bronchitis	Fibroid lung.
-----------	--------------------	---------------

Anæmic States, due to whatever cause (see **ANÆMIA**, p. 25).

Conditions of Debility, even when there is no Anæmia, e.g., after severe illness; after less severe illness, but when there has been much toxæmia, for instance D.A.H. (disordered action of the heart) after influenza, tonsillitis, trench fever, prolonged residence in the tropics, or in association with chronic septic absorption from dental, oral, tonsillar, nasal, bronchial, renal, urethral, vaginal, or intestinal infective processes.

From Poisoning by Chemicals: Especially tobacco smoking, alcohol, lead; or from the effects of inhalation of the products of incomplete combustion of coal gas in gas-fires, or from gas-burners, or from the similar products of petrol-exhaust fumes, lime-kilns, coke-ovens, braziers; as part of the reaction to injection of serum, peptone, or other foreign protein in anaphylactic subjects; from myrtol, the active ingredient of eucalyptus oil; after snake-bite.

Obstruction to the Larynx or Trachea:—

Acute œdema of the larynx	Œdema due to potassium iodide
Acute abductor paralysis	Laryngeal crises of tabes dorsalis
Post-pharyngeal abscess	Foreign body
Cervical caries	Enlarged thyroid gland
Angina Ludovici	Enlarged thymus gland
Laryngeal diphtheria	Aortic aneurysm
Laryngismus stridulus	Mediastinal new growth
Catarrhal laryngitis, especially at the onset of certain cases of measles	Malignant glands in the neck
Acute pneumococcal or streptococcal laryngitis	Lymphadenomatous glands in neck
	Irruption of a caseous gland into the trachea
	Œsophageal tumour.

Acute Obstruction of the Bronchi and Bronchioles :—

Acute bronchitis	Foreign body
Acute capillary bronchitis	Epithelioma of a bronchus
Acute bronchopneumonia	Epithelioma of the trachea
Asthma	Syphilis of the trachea
Whooping-cough	Syphilis of a bronchus.

Lung Disease or Pleural Disease :

Acute pneumonia	Pneumonoconiosis	Hæmorrhax
Bronchopneumonia	Hypostatic pneumonia	Pneumothorax
Fibroid phthisis	Infarct of the lungs	Bronchorrhœa
Bronchopneumonic phthisis	Pleurisy with effusion	Acute œdema of the lungs.
Miner's phthisis	Pleural effusion	
	Empyema	

Mediastinal Masses :—

Aneurysm	Enlarged thymus	Dermoid cyst
Huge heart	New growth	Hydatid cyst.

Enormous Distention of the Abdomen by :—

Ascites	Tympanites	Solid or cystic tumours.
---------	------------	--------------------------

After Chest Injury.**Functional Causes :**

Hysteria	Neurosis	Fright.
----------	----------	---------

When dealing with a case in which the dyspnœa is pronounced and persistent, it is generally not difficult to decide with some degree of accuracy which main category the cause comes into—cardiac, laryngeal, pulmonary, abdominal—as the result of going carefully into the history and then examining the different systems in a routine way. The chief difficulties arise in cases in which the dyspnœa is relatively slight—perhaps occurring only on exertion—and one is uncertain whether it is due to something serious, such as coronary artery disease of grave omen, or to something relatively trivial, such as the smoking of too many cigarettes.

By far the most important organic cause of dyspnœa on exertion, in a patient who is not acutely ill, is *heart trouble* of some kind or another, and the differential diagnosis of the variety of cardiac lesions, and whether it results from valvular disease, from myocardial degeneration, from arteriosclerosis, from granular kidney, or from difficulties in the pulmonary circulation such as result from chronic bronchitis and emphysema or from fibroid lung, has to be decided upon various grounds that are discussed on p. 17. In difficult cases, however, it may be beyond the powers of all our diagnostic armamentarium

even with the assistance of the electrocardiograph and the polygraph, and measurements of the cardiac diameters with the X-ray screen—to decide just how much myocardial or coronary artery trouble there may be behind dyspnœa on exertion: in some cases one may form a grave impression, yet the patient lives subsequently for twenty years; in another case one may take a favourable view, and the patient may be found dead in bed, or drop dead in the street, within a month. Broadly speaking, the age of the patient counts for a great deal in forming an impression: in any man past fifty, seemingly in good health, and hitherto free from symptoms, the development of some dyspnœa and distress in walking up the incline of the Haymarket when there is no difficulty in walking along on the level, should be regarded as a serious omen, indicative as a rule of coronary artery sclerosis if there are no physical signs pointing to some other affection: precisely similar symptoms in a younger man may be of relatively little moment from the point of view of immediate danger, for they may be due to nothing worse than the smoking of too many cigarettes, or the after-effects of some mild toxæmia which has caused D.A.H. (disordered action of the heart) for the time being—a state of affairs seen in very pronounced degree in soldiers who have had mild influenza or trench fever or some other toxic malady, have then engaged upon severe marching exercise, and have found themselves unable to accomplish it because of palpitations, precordial discomfort or actual pain, shortness of breath, giddiness, and a sense of inability to carry on ('soldier's heart'). There is no simple rule to guide one in deciding whether such symptoms are due to non-dangerous neuro-myocardial causes on the one hand, or to grave myocardial or coronary causes on the

other; each case has to be decided on the basis of previous clinical experience, and the ablest physician is certain to be wrong sometimes in his decision between the one group and the other. The older the patient, the slower should one be in deciding that the cause is trivial.

When dyspnœa is due to *obstruction to the larynx or trachea*, the fact is generally obvious on account of other symptoms, such as stridor, up-and-down movements of the larynx itself, sucking in above and below the clavicles and of the lower intercostal spaces, the main difficulty in some of these patients being to decide whether the obstruction is sufficiently near the larynx to be relieved by tracheotomy, or whether it is due to mischief lower down in the trachea, bronchi, or bronchioles. The nearer the obstruction is to the larynx, the greater will be the spasmodic up-and-down movements of the thyroid cartilage, and the stridor. If the evidence is that the obstruction is in the larynx itself, and if the

dyspnœa is extreme, the probability is that tracheotomy will be resorted to as an urgency measure, the precise diagnosis being determined later. The history, or a local examination, would serve to diagnose or exclude acute *abductor paralysis*, *post-pharyngeal abscess*, *foreign body*, *enlarged thyroid gland*, *malignant glands in the neck*, *lymphadenomatous glands in the neck*. *Enlargement of the thymus gland* can seldom be more than conjectured, or diagnosed by a process of exclusion, unless there is a definite percussion dullness behind the upper part of the sternum in a child under ten years of age, together perhaps with an X-ray shadow of the gland (*Fig. 213*). *Aortic aneurysm or mediastinal new growth* obstructing the trachea will generally have given rise to other characteristic symptoms; particularly, in the case of mediastinal new growth, to obstruction of the innominate veins or the superior vena cava, with varicose distention in the superficial thoracic veins by way of collateral circulation (*Fig. 218*, p. 260). The X rays may be useful in confirming the diagnosis (*Fig. 214*, and see *Fig. 219*, p. 260).

In a great many cases, particularly in children, none of the above will be the least likely, and if foreign body

Fig. 213. Skilgram showing an enlarged thymus gland. There were no thoracic symptoms; the large thymus was discovered in the course of a routine X-ray examination on account of dyspnœa in a female, age 18. T, Shadow of the large thymus. H, Shadow of the heart. D, Shadow of the diaphragm. (*By Dr. C. Thurston Holland.*)

and post-pharyngeal abscess have been excluded by digital examination, the first suspicion will be that the patient is suffering from *laryngeal diphtheria*. This may be confirmed by the presence of a small quantity of membrane on the pharynx, the uvula, or elsewhere, though quite commonly when laryngeal diphtheria is extensive there is no obvious exudate upon any of the visible parts at the back of the mouth. The existence of cases of diphtheria in the same house or in the neighbourhood may point to the diagnosis; but in every case swabbings should be obtained from as far back in the throat as possible, and examined for Klebs-Löffler bacilli, both in direct films and by culture. Until laryngeal diphtheria can be excluded by the absence of Klebs-Löffler bacilli—and a single negative result does not necessarily exclude the disease—the nature of the case will probably remain in doubt. *Acute œdema of the larynx* is nearly always due to some microbial infection, and therefore in a sense it includes acute pneumococcal or streptococcal laryngitis, the diagnosis of which depends upon bacteriological

cultivations from swabbings from the throat. (Edema may also be due to similar infection of ulcerated places in the throat developing in the course of *tuberculous, syphilitic, malignant, lupoid, leprous, traumatic, or post-typhoidal laryngeal ulceration*. The previous history, with the results of examination of the lungs, larynx, and sputum, will indicate the diagnosis.

The *laryngeal crises of tabes dorsalis* are exceedingly rare: they might be suggested if the patient were known to have no knee-jerks and Argyll Robertson pupils, but even then there might be doubt as to whether they were really crises and not the result of syphilitic ulceration, or due to the administration of potassium iodide. Acute edema of the larynx is sometimes spoken of as one of the complications of *acute Bright's disease*, but it is very rare in this malady, rarer than acute edema of the lungs: it is usually a terminal factor, the diagnosis of nephritis having been made previously on account of albuminuria with tube-casts and perhaps general edema. *Laryngismus stridulus* is a dangerous diagnosis to make, for many cases thought to be this are really examples of diphtheria: laryngismus stridulus, when it does occur, is to be expected in rickety children who show a tendency to spasmodic muscular contractions in other parts besides the larynx, such for instance as convulsions from slight causes, or the carpopedal contractions of infantile tetany ('spasmophilia'), but no such cases should be diagnosed as simply neuro-muscular spasm until every precaution has been taken to exclude all other causes of laryngeal obstruction, especially diphtheria, post-pharyngeal abscess, or a foreign body. Now and then one meets with a case in which an apparently healthy child is seized suddenly with acute dyspnea, cyanosis, orthopnea, and general respiratory distress, without any signs of laryngeal obstruction, the result of *irruption of a caseous bronchial or mediastinal gland into the lower part of the trachea or a main bronchus*. The symptoms are precisely such as one would expect if the patient had suddenly inhaled a foreign body of some size, and if one can be quite sure that no such foreign body has been inhaled, the correct diagnosis may sometimes be guessed at. It would be confirmed if, as occasionally happens, a sudden effort of coughing leads to the caseous or crumbly mass being expectorated.

The difficulty of being certain whether, in a given case of severe respiratory distress with evidence of obstruction, the mischief lies in the larynx or in the lungs, is sometimes considerable: in either case there may be marked cyanosis, orthopnea, dyspnea, sucking in above and below the clavicles and of the lower intercostal spaces: the most important point to note is whether the larynx itself remains stationary as when the mischief is in the lungs, or whether it moves up and down with the respiratory movements as it does when the trouble is in the larynx. Very often both the lungs and the larynx are involved, and it may then be difficult to decide which is the more so, and consequently whether tracheotomy is indicated or not. The chief point on which to lay stress, besides the movements of the larynx, is the result of a physical examination of the chest for evidence of *acute bronchitis or of bronchopneumonia*.

True *asthma* is a spasmodic variety of dyspnea, the diagnosis of which, and the difficulty of distinguishing between asthma complicated by bronchitis and bronchitis simulating asthma, are discussed elsewhere (p. 653).

Fig. 214. Sialogram showing two aneurysms of the aorta. One aneurysm (A) affects the ascending aorta, the other (B) the first part of the descending aorta. (By Dr. W. H. Courtonne.)

Whooping-cough is easy to diagnose when the patient exhibits the typical whoop, but sometimes no whoop occurs, the patient exhibiting merely severe paroxysms of cough and dyspnœa, possibly leading to vomiting; if relatives or friends have been affected by whooping-cough recently one may guess the diagnosis, but in some cases it remains a matter of surmise even if the blood serum gives a positive Bordet-Gengou reaction.

Mediastinal masses, such as aneurysm, a huge heart, new growth, hydrothorax with marked displacement of the heart, and *enormous distention of the abdomen* by ascites, tympanites, or by large tumours, will generally have been diagnosed by reason of other symptoms besides dyspnœa. The chief reason why a very large heart or a thoracic aneurysm may produce dyspnœa and orthopnœa, even when there are no signs of failure of the cardiac compensation, is that when the patient sits up there is a greater distance between the sternum and the vertebrae than when he lies back. The cause for the orthopnœa is thus mechanical, the patient sitting up to allow a bigger space for the accommodation of the abnormal mass; hence in some of these cases he may be able to walk about and see to his business without distress during the daytime, and yet be unable to lie down at night. The cause of the orthopnœa associated in this way with a huge heart is quite different from that in which there is failure of the right side, the former being a mechanical means of giving a big mass more room, whilst the latter is due to the need of maximum assistance from the respiratory blood-pump.

Herbert French.

DYSTOCIA signifies difficult birth or labour. The difficulties of delivery show themselves by prolongation or delay in the completion of the stages into which labour is usually divided. Difficult labour is accompanied by progressive symptoms, objective and subjective, which are to be explained by physiological exhaustion, especially in its effect upon the central nervous system of the patient. The results of difficult labour are thus of such importance, affecting, as they do, the life of the mother and child, that anticipation of it, and therefore early and appropriate treatment, are of paramount importance in scientific midwifery.

The causes may be tabulated according as they occur in the first or second stage, the first series delaying the dilatation of the cervix, the second the expulsion of the child. It is not out of place in this connection to add also the causes of difficulties in the separation and expulsion of the placenta, for delivery cannot be said to be complete until the placenta is expelled.

CAUSES OF DELAY IN COMPLETION OF THE THREE STAGES OF LABOUR.

FIRST STAGE	SECOND STAGE	THIRD STAGE
Weak uterine contractions	Weak uterine contractions	Weak uterine contractions
Rigidity of cervix: relative, spasmodic, cicatricial, new growths	Secondary uterine inertia	Morbid adhesion of placenta
Pendulous belly, causing ante-version	Absence of accessory muscular effort	Uterine spasm
Early rupture of membranes, due to malpresentations, morbid adhesions to the lower uterine segment, undue friability	Contraction ring	'Hour-glass' contraction
Malpresentations in general	Rigidity of vagina and perineum	Adhesion of membranes
Anything which prevents the head entering the lower uterine segment	Loaded rectum	
Hydramnios	Distended bladder	
Deficiency of liquor amnii	Cystocele	
Twins	Contracted pelvis	
	Pelvic tumours: Fibromyoma, ovarian tumours, growths of the pelvic bones, hamatoma, varicose veins, vaginal growths	
	Malpresentations: Occipito-posterior, breech, face, brow, transverse	
	Any abnormal enlargement of the child: Hydrocephalus, meningocele, ascites, tumours, double monsters, very large child	
	Excessive ossification of the head	
	Short cord: absolute, relative	
	Locked twins	

From the above it will be seen that the causes of delay are very numerous and important; and the successful delivery of the child under many of these conditions depends very much on their *anticipation*, rather than their recognition when delivery is already dangerously obstructed. Consequently, accurate diagnosis at the beginning of labour will often save much trouble to the practitioner, and danger to the mother and child. Indeed, some of the dangers of obstructed labour can only be avoided satisfactorily by careful examination of the patient during pregnancy, say at the thirtieth week. This applies specially to the recognition of contracted pelvis, of pelvic tumours, and sometimes of malpresentations, and constitutes an important reason why every patient should be urged to undergo an examination during the later weeks of pregnancy.

The routine method of examination of the pregnant woman, whether in labour or not, is the same; and the deductions to be made from it are identical. The examination is made as follows: first, by abdominal palpation; secondly, by vaginal examination.

Abdominal Palpation. First feel for the fetal head in the pelvis by the 'pelvic grip'. In a primipara the head should be well down in the pelvis; not necessarily so in a multipara. Failing to find the head in the pelvis, palpate for it at the fundus; failing to find it here, it will be found in one or the other lateral situation. If the head is in the pelvis, and fixed, there can be no pelvic contraction of importance, and tumours of the uterus or ovaries *below the brim* are quite unlikely. If, however, the head is above the brim and movable in a primipara, pelvic contraction must be suspected, whilst a tumour preventing entrance into the pelvis is a possibility. Pelvic contraction may be verified by pelvimetry, for which see below. Abnormal presentations are recognized by abdominal palpation: breech and transverse by the actual position of the head: occipito-posterior by the presence of the 'small parts'—arms and legs—in front, and the absence of the back of the foetus; a face cannot be diagnosed absolutely except in mento-posterior cases, when the groove between the extended occiput and back will be felt in front whilst the head remains above the brim. *Hydramnios* may be recognized if there is fluctuation and the foetal parts can only be felt by deep dipping through the fluid. *Twins* may possibly be recognized by feeling two heads, and hearing two foetal hearts beating with different rhythms.

Vaginal Examination. It is important to remember that very little can be made out with one or two fingers. As a rule, all that can be noted is the *condition of the canal*, whether narrow or rigid, with a powerfully acting levator ani muscle, and the *condition of the os*: note especially its consistence, and the integrity of the membranes. It may not even be possible to recognize the presentation if this has not been made out by abdominal palpation. If contracted pelvis is suspected, the important diameter, namely, the diagonal conjugate, should be measured with the fingers, and the true conjugate estimated by subtracting half an inch from this measurement. The only accurate instrument for taking this measurement is *Skutsch's pelvimeter*; but its use requires considerable experience, and, in general, the simpler method with the fingers is sufficiently accurate for most purposes. External measurements may be made to supplement the important internal one; but they are not of the same practical importance. When a difficulty arises in labour, accurate diagnosis is indispensable, and the whole hand should be inserted into the vagina under anaesthesia. The presenting part may then be grasped, and its true character determined. In this way occipito-posterior presentations (the commonest cause of difficult labour) can be diagnosed with certainty, and rectified. A contraction ring due to an irritable uterus as a result of attempts at forcible delivery will be felt gripping the foetus and preventing delivery. Hydrocephalus may be recognized by this manoeuvre. The hand may be pushed on above the head without danger in most cases, and the neck felt for coils of cord, the body of the child palpated for the presence of tumours or enlargement by ascites. Tumours obstructing delivery are best felt from the vagina: they are usually wedged between the presenting part and the sacral promontory, part below and part above this prominence. If fluctuating and soft they are usually ovarian cysts; if hard and unyielding they may be fibromyomata of the uterus, but these also are apt to soften during pregnancy, and to feel like fluid tumours. Tumours of the pelvic bones are usually bony or cartilaginous: growths of the cervix may be fibroid, but more commonly are friable carcinomata, bleeding freely on examination.

Little more than the method of examination can be indicated in a short article on the

diagnosis of a case of difficult labour ; but too much stress cannot be laid on the value of abdominal examination and palpation as the most important means of gaining information in any labour.

Delay in the Delivery of the Placenta, though not strictly a part of difficult labour, presents difficulties in the completion of delivery, and must not be overlooked. The placenta may be simply retained in utero : may be adherent to the uterus, totally or partially ; or may be retained in the vagina. In the first case, if there is no hemorrhage, the placenta is likely to lie in the lower uterine segment and vagina, and is not expelled owing to weakness of the accessory muscles. If partially adherent, bleeding is certain to occur, whilst total adhesion does not permit of any bleeding. In any case of this kind, if, after a sufficient time has elapsed, the placenta cannot be expressed, the hand must be introduced into the uterus in order to diagnose the condition. It must not be forgotten that the placenta may be retained above a spasmodic stricture of some part of the uterus, the so-called *hour-glass contraction*. Hemorrhage always accompanies this condition if the placenta is partly separated.

The Symptoms of Exhaustion consequent upon Obstructed Labour may finally be mentioned. The first are rise of temperature and increase in frequency of the pulse-rate. These afford very important indications of obstructed labour, and assist us to distinguish this from simple delay from weak uterine contractions, in which the pulse and temperature remain normal. The later symptoms of obstruction, if not relieved, are local and general. Locally, the vaginal secretions fail, the parts become hot, dry, and swollen. The uterus contracts powerfully, and may go into a tetanic condition, usually known as tonic contraction, in which case the uterus is hard, never relaxing, and is tender to the touch. The exact opposite occurs in uterine inertia, when the uterus remains flaccid, along with a normal pulse and temperature. Later still, vomiting may occur, signs of septic infection may appear, and rupture of the uterus may take place owing to the dangerous thinning of the lower segment when tonic contraction supervenes. This series of symptoms should never occur in properly conducted midwifery ; their possible occurrence should always be anticipated by correct diagnosis early in labour, followed by immediate appropriate treatment.

EAR, BUZZING IN.—(See TINNITUS, p. 877.)

EAR, DISCHARGE FROM.—(See OTORRHEEA, p. 521.)

EARACHE denotes pain in or about the ear : in about 95 per cent of cases the pain is inflammatory in origin and the cause will be found on routine examination. In the remaining 5 per cent of cases the pain is either *referred* to the ear or is of organic nervous origin. The cause of earache of inflammatory or local origin lies in the *auricle*, *meatus*, or *middle ear*.

Causes in the Auricle include :—

Injury	Perichondritis	Rodent ulcer	Gnat-bite
Hæmatoma	Gout	Eczema	Bee-sting
Chilblain	Syphilis	Impetigo	Wasp-sting.
Frostbite	Epithelioma	Mosquito-bite	

Causes in the Meatus include :—

Boils	Eczema	Polypus	Epithelioma
Furuncles	Wax	Foreign body	Injury.

Boils, owing to the density of the tissues of the part, may cause very severe pain indeed ; they are frequently multiple, often bilateral, and may occur in the ear without any being present elsewhere on the body ; they may cause the lymphatic glands in front of the ear to be enlarged and tender, also those over the mastoid process. Unless the meatus is completely blocked the hearing is not affected. Sometimes there are no separate boils, but the whole meatus is swollen and inflamed by a *diffuse meatitis*.

Ulceration of the meatus occurs as a complication of otitis media, but may be the result of infection by staphylococci, gonococci, streptococci, the Klebs-Löffler bacillus, or the organisms of Vincent's angina. Occasionally ulceration occurs as a manifestation of secondary or tertiary syphilis.

Causes in the Middle Ear. Inflammation of the middle ear almost invariably follows nasal or pharyngeal catarrh, and in children recurring attacks of earache are suggestive of the presence of adenoids.

Acute otitis media gives rise to intense pain, often intermittent: there is a rise of temperature to 102° F. or more, often 103° or 104° in children; deafness is usually of high degree. Examination shows the tympanic membrane to be generally red, with obscuration of usual landmarks owing to bulging of the whole membrane outwards. In some cases the inflammation proceeds rapidly to suppuration and the drum gives way, allowing escape of pus: in others resolution occurs and the initial redness disappears gradually, the membrane returning to its normal colour. In the majority of cases there is some tenderness over the mastoid process, but this passes as the inflammation recedes.

Acute mastoiditis following acute otitis media gives rise to severe pain in and behind the ear: should pain persist with a free discharge of pus through the membrane (whether that discharge is due to rupture or incision of the membrane) there is presumptive evidence of mastoid involvement. In cases of chronic suppurative otitis media acute mastoiditis may occur, and then cessation of discharge often accompanies the onset of pain. Complications of otitis media, especially lateral sinus thrombosis, cerebral or cerebellar abscess, or meningitis, are causes of pain, but it is not as a rule the predominant symptom in these cases.

Malignant disease of the middle ear gives rise to severe and progressive pain of a boring character: whether the growth (carcinoma) begins in the deep meatus or in the middle ear, it spreads through the bone in the mastoid region.

Some cases of chronic catarrhal otitis complain of pain in the ear.

The Non-Inflammatory Causes of pain in the ear are: (1) *Referred*; (2) *Nervous*.

1. **REFERRED PAIN IN THE EAR.** Owing to the extensive nerve-supply of the external and middle ear drawn from the 5th, 9th, and 10th cranial nerves, as well as from the 2nd and 3rd cervical nerves, pain may be referred to the ear from many other parts— even from the stomach or heart via Arnold's nerve.

Curious teeth, especially the third upper molars, also erupting and unerupted third molars, upper or lower, are a frequent cause of earache. During teething infants are often noticed to rub the ears, presumably on account of referred discomfort.

Inflammatory affections of the *tonsils*— acute tonsillitis, quinsy, and tonsillar abscess—are commonly attended by pain running up to the ears. It is common for earache to be complained of after operation on the tonsil.

Carcinoma or sarcoma of the tonsil or nasopharynx, or malignant disease beginning in the lateral wall of the pharynx, may produce severe earache. *Adenoids* probably cause pain only in so far as they are responsible for slight attacks of middle-ear inflammation. *Syphilitic or tuberculous ulceration of the pharynx* or a *retropharyngeal abscess* may cause pain in the ear.

Ulcerations of the epiglottis or of the larynx, whether septic, tuberculous, syphilitic, traumatic, or malignant, produce pain in the ear, and in cases of acute streptococcal perichondritis of the arytenoid earache is sometimes the only symptom.

Severe pain in the ear may result from involvement of the glands of the neck secondary to *epithelioma of the tongue* or as a part of *angina Ludovici*.

2. **NERVOUS PAIN IN THE EAR.** Geniculate neuralgia (*tic douloureux*) affects the sensory division of the 5th nerve, and the pain may be experienced exclusively in and around the ear: in a few of these cases herpes occurs, the vesicles being on the concha or behind the ear.

In some cases of *herpes of the upper cervical nerves* vesicles are seen in the neck along the course of the small occipital nerve on one side, and there may be complaint of great pain in, or at the back of, the ear. Occasionally deafness and vertigo are associated with the herpes, but if the vesicles are not obvious such cases present considerable difficulty in diagnosis from some acute inflammatory condition of the middle ear or even mastoiditis.

Glossopharyngeal neuralgia— a rare form of neuralgia— affects the 9th cranial nerve: the pain starts in the throat and radiates to the ear: it may be associated with herpetic spots on the tonsil area.

Patients with *tabes dorsalis* occasionally complain of pain in the ears: it may be of the transient, lancinating character that is seen more commonly in the legs in this disease in the form of lightning pains.

EMPHYSEMA, SURGICAL. Surgical or subcutaneous emphysema is due to distention of the subcutaneous areolar tissues with air or gas. The diagnosis of the condition and its cause is not as a rule difficult. Its commonest starting-place is in connection with the thorax, particularly when there has been *injury to the lung* tissue by a broken rib, a stab with a knife, a bullet wound, the rupture of alveoli due to excessive coughing, as in whooping-cough and bronchitis, or during great strain, as in difficult labour ; or by operative injury to the lung, as in exploratory needling of the chest. The gas spreads rapidly, and may extend over the greater part of the trunk in a short time, disappearing again in the course of a few days. It may do so similarly after the operation of *tracheotomy*.

The face may sometimes be almost suddenly involved unilaterally by the escape of air into the subcutaneous tissues from the upper part of the nose, after violent *sneezing* or energetic *blowing of the nose*.

Rarer causes for the escape of actual air into the subcutaneous tissues are *ulcerative* or *traumatic lesions* of the *æsophagus*, *stomach*, *duodenum*, *cæcum*, *bladder*, or *rectum*. Air escaping in the areolar tissues around any of these parts may sometimes extend and become palpable as crepitus under the skin.

Quite another type is that in which the gases in the tissues are not air, but the results of *infection by gas-producing bacteria*. Fortunately cases of this kind are now rare, though many were met with during the great war : they were common in the days of *hospital gangrene* and *putrefaction*. The *Bacillus coli communis*, however, not infrequently liberates gas in an abscess to which it may give rise—for instance in the region of the vermiform appendix—and sometimes subcutaneous emphysema results. Another gas-producing organism that attacks man, though less often as a primary affection than intercurrently during some other malady, is the *Bacillus aerogenes capsulatus* ; this, however, more often produces gas-containing loculi in the liver and other internal organs post mortem than in the tissues beneath the skin during life.

Herbert French.

EMPHYEMA.—(See CHEST, PUS IN, p. 132.)

ENLARGEMENT OF A BONE.—(See SWELLING ON A BONE, p. 817.)

ENLARGEMENT OF THE FOREHEAD.—Many individuals who have passed middle age—males more so than females—tend to develop an increasing prominence of that part of the forehead which corresponds with the outer casing of the frontal air sinuses ; with the result that their eyebrows seem to overhang the eyes more and more, and the countenance looks different from what it did ten or fifteen years before. This is due to slow enlargement of the air cells of the frontal sinuses, and is not pathological. This normal enlargement of the forehead has to be distinguished from two diseases which, though rare, are generally recognizable with ease if the patient is watched over a period of months or years—namely, *leontiasis ossea* and *acromegaly*.

The commonest symptom that a patient suffering from *leontiasis ossea* complains of is that in former years he always took a certain size of hat, and was able to order hats without having to go and try them on ; of recent years, however, he found that he had to get progressively increasing sizes, so that whereas formerly a number 7 may have fitted him, he may now require even so large a size as a number 8 ; in a few exceptional cases special hats have had to be made for the patient because the enlargement of the head, especially

of the forehead, has become tremendous, whilst at the same time it may very likely not be quite symmetrical. The general health remains good, and if the patient does not mind his personal appearance and the size of his hats, he lives for years without suffering any other inconvenience. On the other hand, the bony changes may not be confined to the skull, but may affect the bones of the limbs as well, especially the tibiae: there is probably a relationship between leontiasis ossea and osteitis deformans or Paget's disease of the bones (see p. 194). If the cranium is examined after death it is found that there is no longer any distinction between the hard ivory bone upon the surface and the cancellous bone in the centre: both have assumed an intermediate character, so that the whole bone is more or less of the same texture, very thick and heavy, and in a condition which used to be spoken of as *osteoporosis*. In some cases the change is syphilitic.

In acromegaly it happens very rarely that the frontal bone is affected alone: far more often the affection of the forehead is much slighter than the increase in size of the lower jaw and of the phalanges of the hands and feet (p. 293). If, however, the changes were more marked in the frontal bone or in the bones of the skull generally than in those elsewhere, it is probable that a case of acromegaly would be diagnosed as one of leontiasis ossea. Whereas, however, in acromegaly the bigness of the lower jaw makes the characteristic facies, in leontiasis ossea the prominence of the forehead gives the face that leonine character from which the name of the disease is taken. If the temporal halves of the fields of vision were contracted, and still more if there were bilateral temporal hemianopia, the diagnosis would be acromegaly and not leontiasis ossea. In case of doubt an X-ray

Fig. 215. Skullgram of the skull in a case of leontiasis ossea: showing the extreme thickness of the frontal, parietal, and occipital bones.

plate of the skull would be taken laterally to determine the size of the sella turcica, which might be of normal dimensions in a case of leontiasis ossea (Fig. 215), whereas in acromegaly the sella would be enlarged by reason of the hypertrophy of the pituitary body to which this disease is due.

No other maladies in adults are likely to cause uniform increase in the size of the forehead, but occasionally one meets with tumours of the frontal bone which cause an asymmetrical enlargement of the forehead, the most important of these being the *ivory exostosis* — a non-malignant tumour which may arise from any of the flat bones of the skull: it grows very slowly but enlarges progressively, and in so doing is apt to displace anything which comes in its way, and in the course of many years great deformity of the eye or nose may thus result. The slowness of the growth, and its very hard character generally, point to the diagnosis at once, and an X-ray examination may help to confirm it.

Other asymmetrical enlargements of the forehead may result from *syphilitic nodes* caused by gummatous periostitis terminating in bony organization: *sarcoma of the periosteum*, a very rare primary growth in this region, but when met with suggested by the relative softness of the mass and its rapid increase in size: *secondary malignant disease*, likely to be mistaken for primary sarcoma if no primary growth elsewhere is known, but

ENLARGEMENT OF THE FOREHEAD

diagnosed readily if the existence, now or formerly, of a carcinoma of the breast, thyroid gland, or other part is known.

Any other tumours in connection with the frontal bone are exceedingly rare. The very extensive disease of the frontal, as of any other cranial, bone which used to be met with in syphilitic subjects is now practically unknown on account of the greater adequacy of the treatment of syphilis in its earlier stages.

Leprosy may be mentioned as a cause of enlargement of the forehead (*Fig. 388*, p. 501), for in the nodular form any part may be affected : but it must be very rare for leprosy to affect the forehead region only, and the diagnosis will be suggested by the lesions elsewhere and by the history of the case.

The above remarks apply to enlargement of the forehead in adults. In children quite different causes will suggest themselves, the three most important being : (1) *Hydrocephalus* ; (2) *Rickets* ; (3) *Congenital syphilis*.

It happens not infrequently that a child's forehead enlarges very considerably, and bulges with much convexity to such an extent as to make both the parents and the physician fear hydrocephalus when the child is suffering from nothing more serious than rickets. The diagnosis may be quite difficult if there are not at the same time the other familiar signs of rickets mentioned on pp. 182, 268 : and there are not a few instances in which it is only when the case has been watched for months and years that one can be sure that there

Fig. 216.—Hydrocephalus, showing the huge head and bulging forehead.

is no hydrocephalus. The same applies to the swelling of the frontal bone that may result from congenital syphilis. In the case of both rickets and congenital syphilis one will examine the whole of the head carefully, to try to make up one's mind whether the enlargement, which usually affects not only the forehead but also other parts of the skull, is a more or less uniform stretching such as hydrocephalus gives rise to (*Fig. 216*), or whether there are not some parts which are enlarged and other parts which are more or less normal. Both congenital syphilis and rickets are apt to produce diffuse round prominences of the parietal regions as well as of the frontal regions, so that there are four main bulges with an antero-posterior and a transverse groove between them, constituting the hot-cross-bun-shaped type of head ; but the difficulty of excluding hydrocephalus is made greater still when, as sometimes happens, there is such thinning of the bones in the occipital region from cranio-tabes that the bones can be dented inwards like stiff parchment : such cranio-tabes may result either from rickets or from congenital syphilis. One would then pay special attention to the regions of the sutures : if these are obviously stretched asunder the case is almost certainly hydrocephalus, and not rickets or congenital syphilis. One would also be able to draw some conclusion perhaps from the appearances of the eyes, for the eyeballs will be in normal position when the cause of the forehead enlargement is rickets or congenital syphilis, whilst with hydrocephalus the eyes will give the impression of being displaced : sometimes they look very much deeper set than normal : in other cases they look as though they are depressed as the result of the downward pressure exerted by the excess of fluid upon the roofs of the orbits (*Fig. 217*). If the enlargement and prominence of the forehead dates

from birth or soon afterwards, this will be an argument in favour of hydrocephalus ; if the change develops later in the infant's or child's life, there will almost certainly be a history of a severe attack associated with symptoms of increased intracranial pressure, for probably the commonest cause of acquired hydrocephalus is a preceding attack of meningococcal meningitis from which the child has recovered. The history, therefore, may help in deciding the diagnosis. The optic discs should also be examined, for in a certain number of cases of acquired hydrocephalus there is optic atrophy (*Fig. 420*, p. 519), and this is practically never met with as the result of rickets, and very seldom as the result of congenital syphilis. It is, of course, only when the degree of hydrocephalus is medium that it is difficult to distinguish it from forehead enlargements due to rickets or congenital syphilis. Major degrees of hydrocephalus cause such extreme enlargement of the whole head, coupled with such thinning of the bones and stretching of the sutures, that the diagnosis is almost unmistakable.

Although either simple or malignant tumours may affect the frontal bones, even in an infant or child, they are very rare. They should be diagnosed in the same way as similar tumours in adults. *Chloroma* may perhaps be mentioned specially, rare though it is. The growths in such a case are never single, but as they may develop upon bones they sometimes attract notice first in connection with the cranial bones, and thus perhaps a local enlargement of the forehead may be the first symptom in the case. There is a tendency for the lymphatic glands generally to become enlarged and sometimes the spleen also, and in some respects the malady simulates lymphatic leukaemia. Neoplasm of some kind

Fig. 217. Hydrocephalus: the triangular focus and the depressed eyes are noteworthy.

will be an early suspicion, and the nature of the growth is indicated by the greenish colour of the tumour when it has been excised. The actual diagnosis, however, is made more often post mortem than during life.

The commonest local swelling of the forehead in a child is a *hematoma* resulting from injury, and as the blood-clot is often deep-seated there is sometimes no discoloration of the skin, and some more serious tumour may be thought of until the disappearance of the mass in the course of a week or two proves its simple character. Such a hematoma after a day or two softens in its central part in a remarkable way, leaving very hard raised edges, and on palpation it feels almost as if there were a hard bony ring with an absence of any bone at all in the centre: the first time such a softening hematoma of the forehead is felt one can hardly believe that it is only a hematoma and not an actual hole in the bone covered merely by scalp and skin. The feeling, however, on palpation is so characteristic that, once felt, the condition is readily recognizable in any subsequent case.

Herbert French.

ENLARGEMENT OF THE GALL-BLADDER. (See GALL-BLADDER ENLARGEMENT, p. 314.)

ENLARGEMENT OF THE HEART may be due to hypertrophy of the walls of any of its cavities, but especially of the ventricles: to dilatation of the cavities; or to these two conditions combined.

The most important physical signs of enlargement of the heart are: (1) Displacement of the cardiac impulse; (2) An increased area of cardiac dullness. After puberty the normal cardiac impulse is usually situated in the fifth left intercostal space, about three-quarters

of an inch internal to the left nipple line. Before puberty it is normally in the fourth left space in the nipple line. When the left ventricle is much hypertrophied the cardiac impulse is displaced more in a downward direction than outward, e.g., it may be found in the sixth or even the seventh left intercostal space in the nipple line or outside it. When the enlargement is due to hypertrophy of the right ventricle, the cardiac impulse is displaced more in an outward direction than downward, and frequently there is also considerable pulsation in the epigastrium.

Where the cardiac impulse is thus displaced, before cardiac enlargement is diagnosed the possibility of its mechanical displacement by fluid or air in the right pleural cavity pushing it, or a retracted left lung pulling it, over to the left, must be excluded by careful physical examination of the front and back of the chest. In the case of pleuritic effusion the dullness on the right side of the chest, and the absent or deficient vesicular murmur would point to fluid; in the case of retraction of the left lung the left side of the chest would be smaller, there would be deficient movement, dullness and deficient voice sound and vesicular murmur, or possibly bronchial breathing, consonating râles, and pectoriloquy over the left lower lobe.

The character of the impulse may assist in deciding whether hypertrophy or dilatation preponderates: when it is forcible or heaving, it denotes hypertrophy; when feeble and diffused, dilatation.

The cardiac impulse is invisible and impalpable in some cases of enlargement of the heart, on account of emphysema of the lungs. In these circumstances it may be impossible to determine the dimensions of the heart without an X-ray examination: screening of the thorax and direct measurement of the cardiac diameters with a foot-rule is the most certain method of its size: the transverse measurement of the combined ventricular shadows should not exceed $6\frac{1}{2}$ inches, and the corresponding measurement of the auricles and of the shadow of the aortic arch should not exceed 4 inches and $2\frac{3}{4}$ inches respectively.

Careful mapping out of the area of cardiac dullness may afford valuable information as to the part of the heart involved in the enlargement. If the area of deep dullness is increased downwards and outwards, an increase in the size of the left ventricle is indicated; if upwards and to the right, hypertrophy of the right ventricle; if in all directions, enlargement of both ventricles.

Enlargement of the heart in children may produce definite local bulging of the chest wall in the cardiac area.

Having determined the position and character of the impulse, mapped out carefully the area of cardiac dullness, and thus arrived at the conclusion that the heart is increased in size, the next step is to determine not only what particular part is enlarged, but also the actual cause of the enlargement.

ENLARGEMENT OF THE LEFT VENTRICLE.

The left ventricle may become enlarged in:—

1. **Aortic Disease**:—Stenosis and regurgitation; regurgitation; stenosis; aneurysm of the first part of the aorta involving the aortic ring.
2. **Mitral Regurgitation**:—Disease of the mitral valve; dilatation of the left ventricle involving the mitral ring; secondary to myocardial degeneration or to adherent pericardium.
3. **Arteriosclerosis and Granular Kidney.**
4. **Alcoholism.**
5. **Long-continued Over-exertion**:—Athletes; mountaineers; rowing men; workers at laborious occupations, e.g., stokers, firemen, furnacemen, blacksmiths.
6. **Exophthalmic Goitre.**
7. **Congenital Heart Disease.**

1. AORTIC DISEASE.

Aortic disease may cause very great enlargement of the heart—*cor bovinum* or bovine heart; the normal weight being about 10 ounces, hearts of 50 ounces or more have been recorded.

Stenosis and regurgitation is the commonest form of aortic disease, then regurgitation, and pure stenosis is the rarest.

Aortic Stenosis and Regurgitation result from two chief antecedent causes—acute rheumatism in the young, syphilis in those who are between 40 and 55 years of age. The cardiac dullness is increased to the left and the cardiac impulse is displaced downwards and outwards. It may be in the fifth, sixth, seventh, or even eighth space in or outside the left nipple line, and may be as far out as the anterior axillary line. The further the impulse is down the larger the left ventricle, and the further it is out the more the dilatation. When the impulse is forcible, heaving, and limited, it indicates that hypertrophy predominates; when, on the other hand, the impulse is diffused and feeble, dilatation preponderates. Young people may present well-marked bulging in the precordial area.

A systolic thrill may be felt over the second right intercostal space close to the sternum; more rarely a diastolic thrill may be felt also or independently, either to the right or to the left of the upper part of the sternum, most commonly, perhaps, in the third left intercostal space near the sternum.

A systolic and early diastolic murmur are heard over the base of the heart. The former usually replaces the first sound, is loudest in the second right intercostal space close to the sternum, and is transmitted upwards towards the clavicle and into the carotids. It varies in character, being in some cases soft and faint, and in others harsh, rough, loud. The diastolic might be described as post-systolic, for it replaces the second sound; it is generally soft and blowing, though in rare instances it is harsh or even musical. It may be heard over the upper part of the sternum and on both sides of it, but it is usually best heard in the third left intercostal space close to the sternum. The early diastolic bruit of aortic regurgitation may also be heard at the cardiac impulse. It cannot be mistaken for a mitral stenotic bruit, because there is no interval between the second sound and it. If there is complete compensation, the first sound may be loud and clear at the apex, but if dilatation of the left ventricle has occurred, there may be a blowing, apical, systolic murmur replacing the first sound and traceable outwards into the left axilla. Another bruit, which is rumbling in character and presystolic in time, may be heard at the cardiac impulse when the ventricle is dilated, the so-called *Flint's bruit* (see p. 119).

Patients are often pale, and the carotid, brachial, and other superficial arteries pulsate forcibly. A feeling of faintness on rising from the supine to the erect posture, dizziness, headache, a sensation of throbbing in the extremities, palpitation, dyspnoea, and precordial pain on exertion are early manifestations of this disease. As compensation fails the dyspnoea and palpitation increase, oedema of the legs supervenes, pain becomes worse, and is felt not only over the region of the heart, but tends to radiate into the left shoulder and arm, and it may be followed by attacks of true angina pectoris.

The curious splashing or 'water-hammer' pulse is pathognomonic; it is appreciated best if the radial pulse is felt when the arm is raised, the pulse-wave striking the finger with a sudden sharp jerk, and then as suddenly collapsing. When compensation fails, the pulse-rate may become rapid and the beats irregular and intermittent, as in mitral disease, but earlier in the disease the rate and rhythm are normal.

Capillary pulsation, which may be detected in the lips, finger-nails, and skin, is a very characteristic sign. It can be demonstrated by drawing a finger two or three times across the skin of the forehead or abdomen, so as to produce a line of hyperæmia, which, if watched carefully, will be seen to blush and pale alternately, each blush being synchronous with the pulse.

Aortic Regurgitation. The symptoms are practically the same as in aortic stenosis and regurgitation, but there is no systolic thrill and no well-marked systolic bruit in the aortic area. The pulse is of the typical water-hammer type. The presence of a soft systolic bruit in the second right intercostal space close to the sternum does not indicate aortic stenosis unless there be at the same time a thrill there.

Aortic Stenosis is the rarest form of aortic disease. In addition to the absence of a diastolic bruit at the base, there is a pulse very different from that of the water-hammer type. If there is full compensation the pulse is slow, frequently below 60, and it may be only 40, or less, to the minute. It is usually regular, long-sustained, and of good tension. A sphygmographic tracing shows a slow rise, often with an anacrotic break in the up-curve, a broad summit, and a gradual decline. The mere presence of a systolic murmur in the aortic area, even if its point of maximum intensity be in this region, is not sufficient evidence on which to base a diagnosis of aortic stenosis. A little roughening of a segment of the

aortic valves, slight sclerosis of a valve, atheroma or dilatation of the first part of the aorta, and even anaemia, may give rise to a well-marked systolic bruit in this region. Before diagnosing aortic stenosis of clinical degree one should have a big heart, a harsh systolic bruit in the aortic area, and a corresponding well-marked systolic thrill.

Aneurysm of the First Part of the Aorta is another important cause of hypertrophy of the left ventricle if the dilatation of the aorta involves the aortic ring, increases its circumference, and thus renders the aortic valves incompetent, though the cusps may be individually healthy. In addition to the characteristic pulse and the usual signs and symptoms of aortic regurgitation, there may be several indications which point to an aneurysm of the first part of the aorta as the cause of the aortic incompetence :

Fig. 218.—Obstruction to the superior vena cava by an aortic aneurysm with collateral circulation through the distended superficial veins of the neck and thorax.

There may be a distinct bulging of the thoracic wall involving the first and second interchondral spaces close to the right border of the sternum.

There may be well-marked pulsation in the second right interchondral space and also in the adjacent spaces, according to the size of the aneurysm, close to the sternum ; when not obvious to the hand this may sometimes be detected by the ear laid flat on the chest.

In addition to an increase of the cardiac dullness downwards and to the left, there will be dullness in the second right space close to the sternum.

There may also be some signs of intrathoracic pressure :—

The right carotid pulse may be weaker than the left.

The face and neck may be deeply cyanosed if the aneurysm has extended outwards and has stenosed the superior vena cava (*Fig. 169*, p. 198), though this is of rarer occurrence with aneurysm than it is with mediastinal new growth. There may be a loud systolic-diastolic bruit audible in the second right space over the superior vena cava, with maximum intensity an inch or more to the right of the sternum. The superficial veins over the upper part of the right side of the chest in front may be varicose (*Fig. 218*), and the direction of the blood-current in them may be from above downwards, instead of from below upwards.

The right bronchus may be stenosed if the aneurysm projects posteriorly, with impairment of percussion note and deficiency in the vesicular murmur over the upper lobe of the right lung. The X rays might be used to determine the diagnosis (*Fig. 219*), though the aortic diastolic bruit should serve to distinguish aneurysm from new growth.

The diagnosis is incomplete until the actual cause of the lesion has been determined.

Causes of Aortic Disease.

1. Lesions of the Valves :

Acute endocarditis
Fibrosis after former endocarditis
Infective endocarditis

Sclerosis due to : Strain (persistent), syphilis
alcohol
Rupture of a segment
Congenital malformation.

Fig. 219. Skiagram of a large sacular aneurysm (A) of the ascending part of the arch of the aorta ; B, The distal part of the aortic arch displaced to the left ; C C', Clavicles ; D, Diaphragm ; E, Apex of left ventricle. (By Dr. Alfred C. Jordan.)

2. Dilatation of the Aortic Ring from Aneurysm of the first portion of the Aorta.

1. Lesions of the Valves.

Acute Endocarditis.—Occurs most frequently as a complication of acute rheumatism, chorea, or scarlet fever. The indications of acute inflammation of the aortic valves will be a systolic murmur in the aortic area, and less commonly an early diastolic (post-systolic) murmur, which first becomes audible in the third left space close to the left border of the sternum. If the bruits are already present when the patient is first seen, it may be difficult to decide whether they are due to existing acute inflammation or to fibrosis after former inflammation. They may be noticed to arise whilst the patient is under treatment in bed for acute rheumatism, and then their acute nature will be obvious. In cases in which the bruits are due to acute aortic endocarditis and not to permanent fibrosis, the pulse will have little of the water-hammer type, the heart will not be much hypertrophied, though it may be dilated from acute rheumatic toxæmia, and the bruits will be found, as the days go by, either to diminish or increase in intensity, according as the inflammation of the valves resolves or passes on into permanent fibrosis.

Fibrosis from Previous Endocarditis.—When aortic disease is due to fibrosis from previous endocarditis, there will generally be a history of attacks of acute rheumatism, chorea, scarlet fever, or tonsillitis. There will generally be evidence of organic mitral disease at the same time, and if mitral stenosis be associated with aortic disease, whether there is a history of acute rheumatism or not, the valvular lesions may be considered without doubt to be due to the effects of former endocarditis. The patients are generally children or young adults, though a few survive into middle life.

Infective Endocarditis.—In this form of endocarditis, in addition to the signs and symptoms of aortic disease, there may be others, described on p. 45. In some cases bacteriological examination of the blood detects such organisms as the *Streptococcus pyogenes*, *Staphylococcus pyogenes aureus*, *Micrococcus rheumaticus*, *pneumococcus*, or others.

Sclerosis not due to former Endocarditis:

Strain. Persistent strain is an important factor in the production of aortic disease. Occupations entailing long and continued manual labour, and excessive indulgence in athletics, may thus lead to incompetence. The tendency is not nearly so great, however, in those who have not had syphilis as in those who have: so that sclerosis from strain alone must not be diagnosed unless there be neither a history nor evidence of rheumatism, chorea, syphilis, or alcoholism.

Syphilis.—A history of syphilis, and any manifestations of this disease in the form of pigmented scars on the legs, body, and face, ulceration of the tongue, patches of leukoplakia, ulceration, scarring, or perforation of the palate, necrosis of the nasal bones, etc., would point to this disease as the cause, and this conclusion would be strengthened if there were no previous history of rheumatism, scarlet fever, or chorea. The Wassermann reaction may be positive. The patients are nearly always males who have worked hard, and their first symptoms are often brought on by some undue muscular effort which strains the enlarged heart, or even bursts an atheromatous patch in the diseased valve. Uncommon before forty, the lesion is met with between forty and fifty: in many cases the heart has been passed as normal at forty, whilst at forty-five the aortic regurgitation is extreme. These patients often suffer from severe attacks of angina pectoris, to which they are much more liable than are rheumatic aortic cases.

Alcohol. The constant use of alcohol may be followed by aortic sclerosis. The general appearance of the patient, and the signs described on p. 881, would suggest alcohol as the cause in the absence of any evidence of rheumatism or syphilis, but alcoholism without syphilis leads to definite aortic disease less often than it does to a generally hypertrophied heart which sooner or later exhibits fibroid or fatty degeneration.

Rupture of a Segment of the Aortic Valve.—A rare occurrence, usually brought about by some severe and sudden muscular exertion. The following is an illustrative case. A sailor, who had been examined just previously and passed as sound, was one day pulling on a rope, when suddenly the strain on it was unexpectedly much increased. He made a tremendous effort to prevent the rope slipping through his hands, in doing so fainted, and was picked up in an unconscious condition: on coming round he was very dyspnoic, and complained of pain in the precordial region. A well-marked musical early diastolic murmur was now present in the third and fourth left intercostal spaces close to the

sternum ; as the heart-sounds were normal before the accident, the violent physical effort must have ruptured one of the segments of the aortic valve. The probability is that the valve was previously the site of syphilitic atheroma, without bruit, until the extra strain caused a weak spot to give way suddenly and produce incompetence.

Congenital Malformations of the Aortic Valves.— These are extremely rare, and to be diagnosed with great caution. Less uncommon, but still very rare, is *coarctation of the aorta*—congenital stenosis of the artery itself some inches above the valves ; this is not associated with cyanosis, and may occur without symptoms : the diagnosis depends on the existence of a loud systolic bruit, heard as well between the scapula behind as over the aorta in front, and sometimes transmitted into the axillary and brachial arteries and on up into the carotids, or down into the abdominal aorta.

2. Dilatation of the Aortic Ring from Aneurysm of the first portion of the Aorta is nearly always due to syphilitic atheroma of the aortic walls, and in such a case it will be probable that there is syphilitic disease of the aortic valves themselves also. The dilatation of the aorta ('fusiform aneurysm') will be indicated by definite impairment of note in the second right intercostal space near the sternum, and the X rays will confirm it. It will be next to impossible to assess with any degree of accuracy how much of the aortic regurgitation is due to the dilatation of the ring, and how much is due to the concomitant valve changes.

2. MITRAL REGURGITATION.

As a result of mitral regurgitation the left auricle becomes dilated and hypertrophied, the left ventricle dilated and hypertrophied, and later from backward pressure the right ventricle and auricle may be affected similarly. The chief symptoms are dyspnoea on exertion, palpitation, congestion of the face and lips, cough, possibly hæmoptysis, oedema of the feet and legs, and later albuminuria, ascites, and enlargement of the liver. In the early stages the pulse may be regular, full, and of low tension. When compensation begins to fail the pulse becomes rapid, irregular, and intermittent. The cardiac impulse is displaced downwards and outwards. It may be in the fifth intercostal space in the left nipple line, or outside it, or in the sixth space outside the nipple line. It is usually diffused, and there may be epigastric pulsation. There may be marked bulging of the precordial area in children. A systolic thrill is rare, but it may be felt at the cardiac impulse. The cardiac dullness is increased outwards and downwards, but also upwards and to the right when the right side is involved.

At the impulse there is a systolic murmur, usually of a blowing character, which may either follow or replace the first sound. It is best heard at the cardiac impulse, but it can generally be traced outwards into the left axilla, can sometimes be heard behind at the inferior angle of the left scapula, and can also be traced inwards towards the left border of the sternum. The pulmonary second sound is apt to be accentuated or reduplicated in the second interspace close to the left border of the sternum.

When compensation fails, in addition to the above there may be :—

A systolic murmur, softer than and different in character from that at the impulse, over the lower part of the sternum and the fourth and fifth left interspaces, due to tricuspid regurgitation ; oedema of the feet, legs, and lower part of the body ; abdominal distention from ascites ; enlargement and pulsation of the liver ; signs of hydrothorax ; albuminuria.

A diagnosis of mitral regurgitation is incomplete by itself, for it may be due to different conditions. It is necessary to determine, if possible, the actual cause of the defect.

Causes of Mitral Regurgitation.

1. Lesions of the Mitral Valve :—

Acute endocarditis
Infective endocarditis

Fibrosis the result of former
endocarditis.

2. Dilatation, or Hypertrophy and Dilatation, of the Left Ventricle, without organic changes in the Mitral Valve itself :—

Secondary to aortic disease

Secondary to increased systemic blood-pressure :—

Chronic Bright's disease

| Arteriosclerosis.

3. Diseases of the Myocardium and Pericardium :—

Myocarditis	Pericarditis
Fatty degeneration	Adherent pericardium.
Fibroid degeneration	

4. Acute Dilatation of the Heart from :—

Over-exertion	Acute febrile diseases	After anaesthetics.
---------------	------------------------	---------------------

1. Lesions of the Mitral Valve :—

Acute Endocarditis. Simple acute endocarditis is not a disease *per se*, but occurs as a complication of some other disorder, especially acute rheumatism, chorea, and scarlet fever. It sometimes complicates tonsillitis, which is in many instances a manifestation of rheumatism without any pains in the joints : and in children acute endocarditis may be the only indication of an attack of rheumatism. There are no characteristic symptoms which point to acute endocarditis. If in the course of acute rheumatism the patient complains of a little palpitation, precordial pain, and distress, and it is found that the heart action has increased in rapidity without any increase in the joint affection, endocarditis and myocarditis should be suspected. The temperature chart seldom indicates the complication. At first the position of the cardiac impulse and the heart-sounds remain normal, but if watched from day to day, endocarditis having developed, the impulse will be found to have moved outwards, the first sound becomes prolonged and roughened, then doubled, and in a few days it is either followed or replaced by a localized soft blowing systolic murmur.

Fibrosis the Result of Previous Endocarditis.—If acute endocarditis of the mitral valves does not resolve, the valve-flaps become sclerosed, and in the later stages even calcified. In many cases the circumference of the orifice is narrowed, so that the valve is not only incompetent but also stenosed. A diagnosis of fibrosis after endocarditis as the cause of mitral incompetence may be made if there is a previous history of acute rheumatism or chorea, and independently of such a history if there is evidence of stenosis as well as regurgitation. If actual mitral stenosis can be diagnosed with certainty, it must be due to fibrosis from former endocarditis, though there may of course be recent endocarditis as well.

Infective Endocarditis of the mitral valve suggests itself if there is a mitral bruit, and the symptoms and signs mentioned on page 45 are present at the same time.

2. Hypertrophy and Dilatation of the Left Ventricle :—

Secondary to Aortic Disease.—Aortic disease leads to hypertrophy of the left ventricle, followed after a time by dilatation of that cavity and mitral regurgitation. Marked pulsation of the superficial arteries, a splashing pulse, capillary pulsation, and the systolic and early diastolic murmur at the base of the heart, the former best heard in the second right space close to the sternum, and the latter in the third left space close to the left border of the sternum, would indicate the presence of aortic disease. If the patient has suffered from either rheumatism or chorea, the mitral regurgitation might be due to former endocarditis of the mitral valve, but if the aortic disease is the result of syphilis, hard work, or aneurysm of the first part of the aorta, then it may be assumed that the mitral regurgitation is the result of secondary dilatation of the left ventricle, and not of primary mitral disease.

Secondary to Increased Systemic Blood-pressure due to Chronic Bright's Disease.—Associated with the increased blood-pressure of chronic Bright's disease, the left ventricle hypertrophies, and after a time, when compensation fails, dilates ; mitral regurgitation follows, and may be succeeded by all the signs of backward pressure, such as œdema of the feet and legs, ascites, enlargement of the liver, hydrothorax, hæmoptysis from congestion or infarction of the lungs, and so forth. A patient presenting such a group of symptoms may at first glance be considered to be a case of primary disease of the heart, but a careful investigation will often enable one to determine that the primary changes have occurred in the kidneys. The radial artery may be thickened and tortuous, the tension of the pulse higher than in mitral regurgitation from primary heart disease ; there may be albuminuric retinitis and retinal hæmorrhages ; the urine is variable, for whereas it may formerly have been abundant, of low specific gravity (1008 to 1012), with only a trace of albumin, heart failure may lead to its being diminished in amount, of specific gravity 1020 or more, and albumin may be abundant ; microscopical examination, however, will generally reveal renal tube-casts.

Secondary to Increased Systemic Blood-pressure due to Arteriosclerosis.—In this disease there may be signs of enlargement of the heart, mitral regurgitation, backward pressure, and a thickening of the arteries, and it is often merely a matter of opinion whether a given patient is suffering from arteriosclerosis or from granular kidney; post-mortem examination may reveal both, or arteriosclerosis may predominate when granular kidney has been diagnosed, and vice versa.

3. Diseases of the Myocardium and Pericardium:—

Myocarditis.—Inflammation of the myocardium is associated most frequently with either pericarditis or endocarditis, but occasionally it may occur in acute rheumatism as a primary condition. In one form of the disease there is an infiltration of leucocytes between the muscular fibres—interstitial myocarditis; in another form the actual muscle fibres are involved—parenchymatous myocarditis; and there is a third variety which occurs in pyæmia, especially from bone disease, characterized by the formation of abscesses in the myocardium. The weakened condition of the heart muscle leads to dilatation of the ventricles, and thus to enlargement of the heart. When accompanied by pericarditis or endocarditis, the signs of myocarditis are overshadowed by the symptoms associated with these other conditions. The diagnosis of myocarditis is therefore a difficult matter. If in a case of acute rheumatism there is no evidence of either pericarditis or endocarditis, but there are signs of cardiac failure, a feeble irregular pulse, a good deal of precordial pain and distress, dyspnoea and palpitation, a tendency to sudden collapse, and signs of dilatation of the left ventricle, with a feeble cardiac impulse and a weak first sound, myocarditis may be suspected.

Fatty Heart. The heart may be covered with fat (fatty superposition); fat may infiltrate between the muscular fibres (fatty infiltration); the muscle fibres may degenerate, lose their striation, and contain fat granules (fatty degeneration); or all these conditions may be associated. Fatty degeneration may occur in patches or be general. When general, the heart becomes enlarged from dilatation as the muscle becomes flabby, loses contractile force, and is more yielding. It is a condition which may be associated with general obesity, severe anæmia, wasting diseases such as cancer, phthisis, phosphorus poisoning, and alcoholism. It may be a sequela of severe attacks of typhoid and other specific fevers. The symptoms and signs of the condition are due to the diminished contractile power of the ventricles which leads to dilatation. The pulse may be small, feeble, and slow—30 to 40 beats per minute—or it may be rapid and irregular. The cardiac impulse is feeble or imperceptible. There may be an increased area of cardiac dullness from dilatation, and the first sound may be faint. The patient is usually feeble and anæmic, or fat and flabby, and suffers from faintness or syncopal attacks which come on suddenly and are characterized by coma, convulsive twitching, and stertorous breathing. There is dyspnoea on exertion, a feeling of coldness and depression, and a general impairment of the nutrition of the muscles, which are soft, flabby, and diminished in power. In some cases attacks of cardiac 'asthma' in the early morning are complained of, and in the later stages of the disease there may be Cheyne-Stokes breathing. The chief diagnostic signs are the feeble cardiac impulse, the feeble pulse, and the weak first sound, associated with dyspnoea and attacks of syncope, and the absence of evidence of other causes for the heart symptoms.

Fibroid Heart.—Fibroid degeneration of the myocardium is usually associated with some obstructive lesion of the coronary arteries caused by syphilis. It may be general, or rarely localized to the apex of the left ventricle; in the latter case there may be thinning and weakening followed by aneurysm of the heart, and then by rupture—one of the causes of sudden death. The most important symptoms are: dyspnoea on slight exertion, palpitation, and precordial pain. The physical signs are those of dilatation of the left ventricle. The pulse is slow so long as compensation remains good, but with failure of compensation it becomes rapid, and in late stages feeble and irregular. There may be severe attacks of angina pectoris. The diagnosis is more or less a matter of guess-work. Such signs and symptoms in a patient who has had syphilis, but neither acute rheumatism nor chorea, and who has neither aortic disease nor signs of granular kidney or arteriosclerosis, might be considered indications of this form of cardiac degeneration.

Pericarditis.—In pericarditis the cardiac impulse is usually displaced, and the area of cardiac dullness increased. These physical signs may be due to enlargement of the

heart, or to effusion of serous fluid into the pericardial sac, and it is very difficult to differentiate between these two conditions. Enlargement of the heart due to dilatation is generally the result of the myocardium being affected as well as the pericardium, and the cardiac impulse is diffused and displaced outwards. If there is an effusion of serous fluid into the pericardial sac it is said that the impulse is displaced *upwards* as well as outwards, so that it may be found on a level with, or above and external to, the left nipple, but this is a very unreliable sign. The dullness is increased laterally and upwards, and when carefully mapped out it is said to have a triangular shape, with the base on the diaphragm and a somewhat rounded apex pointing towards the left clavicle, and reaching to the second left intercostal space or higher. Percussion, however, is quite unable to distinguish between a pericardial effusion and a much enlarged heart without effusion. The intercostal spaces are filled out, and may be almost obliterated, so that the ribs feel much less prominent on this part of the chest. On auscultation, in addition to a systolic murmur at the impulse due to mitral incompetence from the accompanying dilatation of the left ventricle, a triple 'cantering' sound, and perhaps a definite shuffling rub, may be heard in some part of the precordial region, especially near the sternum, independently of respiration, and generally increased in intensity by firm pressure of the stethoscope. The rub is audible whether effusion is present or not. X rays are an aid in such cases (Fig. 220), but their use necessitates the employment of apparatus that can be brought to the patient's bedside.

Adherent Pericardium. Adhesions between the visceral and parietal layers of the pericardium are found frequently post mortem when they had never been suspected during life. Sometimes, however, they are associated with chronic mediastinitis, or what should more correctly be termed mediastinal fibrosis, the outer surface of the pericardial sac becoming adherent to the thoracic wall and to adjacent structures. This condition usually leads to considerable hypertrophy and dilatation of the heart. There may be marked bulging of the precordial area to the left of the sternum. The cardiac impulse

Fig. 220. Skigram from a case of acute pericarditis with effusion in a young adult. Note that the right side of the shadow remains almost straight, that the degree of enlargement of the pericardium is pronouncedly upwards as well as laterally, and that it is difficult to distinguish the contour of the heart itself in the mass of the shadow produced by the pericarditic effusion.

may be seen not only in the sixth space outside the left nipple line, but also in the fifth, fourth, and third left spaces, and the pulsation may extend in these spaces from the left border of the sternum to the left nipple line, or even outside that line. The impulse has a curious wavy character, and it may be noticed that coincident with the impulse in the sixth space there may be a systolic retraction of the spaces above, or of the lower ribs below and outside the cardiac area. There may be visible systolic movement of the ninth, tenth, or eleventh ribs or intercostal spaces posteriorly, below the angle of the left scapular (Broadbent's sign), best seen when the profile of the back of the chest is watched in a good light. Some cases of adherent pericardium of this type exhibit dilatation of the superficial veins in the precordial area. Diastolic collapse of the cervical veins is said to occur also. On rolling the patient from side to side it is found in many cases that the cardiac impulse remains nearly in the same position, not altering so much as it does in health under similar circumstances. The hand placed over the heart may feel a diastolic shock or rebound, which is regarded by some as a characteristic sign of the condition. On auscultation there may be a systolic murmur at the apex, indicative of mitral regurgitation, and

frequently there is also a presystolic murmur due to a relative stenosis of the mitral orifice. The diagnosis is often guessed at rather than made; if in a young person who has presumably rheumatic fever, the size of the heart is not easily accountable for by the extent of valvular disease suggested by the bruits, the patient probably has adherent pericardium as well.

4. Acute Dilatation of the Heart:—

From Over-exertion.—Acute dilatation may result from over-exertion. For example, if a man who has been run down from excessive mental work, and in consequence is in poor condition or bad training, takes a holiday, and attempts the ascent of a mountain or engages in some violent form of exercise, his heart is very liable to dilate under the strain. The chief indication of such an occurrence will be a feeling of pain, distress, and discomfort in the region of the heart, dyspnoea, and palpitation. The pulse will be rapid, weak, and irregular. The cardiac impulse will be displaced outwards, diffuse, weak, and undulating in character, and although a maximum point of the impulse may be visible, it cannot be located clearly by palpation. The cardiac dullness will be increased outwards, and the first sound will be feeble, reduplicated, or replaced by soft blowing systolic murmur.

From Acute Specific Fevers.—Similar signs and symptoms, especially weakness of the first sound, occurring in the course of diphtheria, typhoid fever, typhus, scarlet fever, erysipelas, lobar pneumonia, and other fevers, would point to dilatation of the heart in consequence of the toxæmia producing loss of tone in the cardiac muscle from parenchymatous degeneration.

3. ARTERIOSCLEROSIS AND GRANULAR KIDNEY (see p. 17).

4. ALCOHOLISM.

Patients who have been addicted to alcoholism are liable to enlargement of the heart: the condition known as 'primary alcoholic heart' is commoner in beer-drinkers than in those who take other forms of alcohol; and particularly in those who drink large quantities of beer daily—brewers' draymen, for example. The enlargement may be considerable. At a post-mortem examination it is by no means unusual to find the heart weighing as much as from 20 to 30 ounces. The valves may be healthy, the aorta normal, and evidence of arteriosclerosis and granular kidney absent. Alcoholism may be suspected as the cause of enlargement of the heart where there is no evidence of primary valvular disease, adherent pericardium, arteriosclerosis, or chronic Bright's disease, and when the patient's habits are known.

5. LONG-CONTINUED OVER-EXERTION.

This produces hypertrophy of the ventricles; for a long period there may be no symptoms, but after a time, when compensation fails owing to the hypertrophy being insufficient to continue the excessive work, dilatation ensues, and mitral incompetence and signs of backward pressure result. The subjects of this form of enlargement of the heart are usually either middle-aged men who are robust and healthy in appearance, but have had to follow for many years a laborious occupation entailing severe manual labour or else young men of good physique who have indulged in excessive athletic exercises, such as rowing, football, boxing, and running, often with insufficient preliminary training. At first, palpitation, dyspnoea, and irregular cardiac action are noticed; later the ventricles dilate, the mitral valves become incompetent, and all the signs of backward pressure may follow. Enlargement of the heart from this cause is much more liable to occur where the patient is accustomed to take a considerable amount of alcohol. As a cause of enlargement of the heart it should not be diagnosed until primary valvular disease, granular kidney, and arteriosclerosis can be excluded.

6. EXOPHTHALMIC GOITRE.

In this disease moderate enlargement of the heart, as shown by the displacement outwards of the cardiac impulse and the increased area of cardiac dullness, is common, and is probably the result of the long-continued increased rapidity of cardiac action. It is

rarely, however, the most prominent sign of the disease. It is distinguished from other forms of enlargement by the presence of tachycardia—the pulse-rate in a well-marked case varying between 120 and 160, or being even higher than this—the marked pulsation of the carotids and other superficial arteries, the exophthalmos, the enlargement and pulsation of the thyroid gland, the fine tremor of the extremities, the loss of weight, the excitability, and the pigmentation of the skin and eyelids. There is very often a loud blowing systolic bruit in the pulmonary area, less often one at the impulse, but frequently one over the thyroid gland. Certain signs associated with the names of von Graefe, Stellwag, and Moebius are not of the least value in making the diagnosis. Derangement of the heart's action may persist even when the other phenomena of Graves' disease have abated; and the patient may ultimately exhibit the phenomena of auricular fibrillation in a degree comparable to what is more often met with in the late stages of mitral stenosis.

7. CONGENITAL HEART DISEASE.

There are a variety of congenital heart deformities—single auricle, single ventricle, transposition, and so forth—but only three forms are at all commonly compatible with survival for any number of years. These are (i) Pulmonary stenosis; (ii) Patent interventricular septum; (iii) Patent ductus arteriosus. Any one of these may occur singly; or more than one may be co-existent in the same case. It is not essential that the dimensions of the heart should be abnormal as a consequence; but in a considerable proportion of cases the heart is either enlarged generally, or there is hypertrophy of one or other of the ventricles.

If there is pure *pulmonary stenosis* without patency of the interventricular septum there is not necessarily cyanosis or clubbing of the fingers; it is the right ventricle which is enlarged; and in the second left intercostal space near the sternum there is a systolic thrill associated with a loud systolic murmur which, though loudest in the same situation as the thrill, is to be heard over a very wide area both in front of and at the back of the chest.

If there is pure *patency of the interventricular septum*, without other defect, the heart is not necessarily enlarged on either side, there is not necessarily cyanosis or finger clubbing, but if there is a bruit at all, it is a blowing systolic one, often with a thrill, with maximum intensity in the third or fourth left intercostal spaces close to the sternum, but audible also over the greater part of the back and front of the chest in some cases. Its maximum intensity is at least a space lower down than is that of pulmonary stenosis. There may be no symptoms of ill health at all.

If there is a combination of both pulmonary stenosis and patency of the interventricular septum, there is a systolic bruit, with thrill as a rule, with maximum intensity in either second or third intercostal spaces; but the bruit is also audible over a wide area besides. The patient suffers from typical *morbus caruleus*, with cyanosis, polycythæmia, clubbed fingers and toes, and pronounced dyspnoea on exertion.

Patent ductus arteriosus, when it occurs without other cardiac defect, is compatible with longevity and freedom from symptoms. It is diagnosed by the occurrence in the second and third left intercostal spaces of an almost continuous bruit, described as systolo-diastolic because it runs through the whole cardiac cycle; but it waxes and wanes in such a way that its maximum intensity is at the time of the second sound, a point which gives the diagnosis at once because there is no other bruit like it. There is often a corresponding thrill. The patient is not cyanosed, has not clubbed fingers, and is often not liable to any particular dyspnoea.

Patent foramen ovale is sometimes propounded as a clinical diagnosis, but there are neither signs nor symptoms produced by the lesion, which is no more than a fairly common anatomical peculiarity.

ENLARGEMENT OF THE RIGHT VENTRICLE.

When the enlargement of the heart is due to hypertrophy or dilatation of the right ventricle, the cardiac impulse is displaced outwards more than downwards, there is frequently well-marked epigastric pulsation, and the dullness is increased upwards and to

the right rather than to the left. The causes of enlargement of the right ventricle are as follows :

1. Diseases of the Left Side of the Heart :—

Mitral stenosis

All the conditions which cause enlargement of the left ventricle (p. 258).

2. Diseases of the Lung :—

Fibroid lung

Chronic bronchitis and emphysema.

3. Diseases of the Right Side of the Heart :—

Congenital pulmonary stenosis

Pulmonary incompetence : (i) Due to dilatation of the pulmonary artery ;

(ii) Due to infective endocarditis of the pulmonary valve.

1. DISEASES OF THE LEFT SIDE OF THE HEART.

Mitral Stenosis.—This is a common and most important cause of enlargement of the right ventricle. The obstruction to the flow of blood from the left auricle into the left ventricle leads to hypertrophy and dilatation of the left auricle, passive congestion of the lungs, red and brown induration of these organs, thickening, dilatation and atheroma of the branches of the pulmonary arteries in the lungs as a result of the increased tension in these vessels. All these changes increase the amount of work to be performed by the right side of the heart, and are responsible for the hypertrophy of the right ventricle, by which means compensation may be maintained for some time. When the right ventricle gives way compensation fails. In the early stages the pulse shows little variation from the normal, and there may be no obvious symptoms pointing to the existence of mitral stenosis. In more advanced phases the pulse becomes rapid, small, and irregular, especially when auricular fibrillation has supervened. The cardiac impulse is displaced outwards, and pulsation occurs in the epigastrium and in the third, fourth, and fifth intercostal spaces close to the sternum. On placing the palm of the hand over the region of the cardiac impulse and the adjacent fourth and fifth intercostal spaces, a characteristic thrill may be felt ; it is diastolic in rhythm, mid-diastolic or presystolic ; and when the latter, it may be felt to terminate suddenly in a sharp shock which is synchronous with the apex beat. The precordial dullness is increased upwards from the third left rib to the second, or even higher ; it extends well to the right of the sternum, but it does not reach far to the left, though in a few cases it extends to the left nipple line even when mitral stenosis is the only lesion present. The more the dullness extends to the left, however, the less likely is the diagnosis of mitral stenosis alone to be correct. At or just inside the cardiac impulse, often over an area which is extremely localized, a loud, rough, rumbling, vibrating bruit may be heard, which runs up to, and is continuous with, a loud, accentuated, slapping first sound, which may or may not be followed by a systolic murmur. This characteristic presystolic bruit may occupy more than half the diastole, increasing in intensity until it finally ends in the loud first sound. It may, however, be mid-diastolic, commencing in the middle or latter part of diastole, with an interval between it and the preceding second sound, and an equally clear interval between it and the subsequent first sound. The other abnormal signs to which mitral stenosis may give rise are described on pages 118 and 119.

All the Conditions which cause Enlargement of the Left Ventricle.—Whenever compensation begins to fail in cases of mitral regurgitation from any cause, aortic disease, enlargement of the left ventricle from chronic Bright's disease, arteriosclerosis, alcoholism, or other causes discussed above, and there is backward pressure through the lungs, hypertrophy of the right ventricle serves to maintain compensation for a time. The increase in the size of the right ventricle would be indicated by the advent of epigastric pulsation and a further increase of the dullness to the right of the sternum, but the diagnosis of its cause would rest upon data already discussed under the heading of mitral regurgitation (see p. 262).

2. DISEASES OF THE LUNG.

Fibroid Lung gives rise to symptoms and physical signs so characteristic that there is rarely any difficulty in making a diagnosis. The hypertrophy of the right ventricle is

of secondary importance, and does not become manifest until late in the disease. The retraction of the lung draws the heart over towards the affected side, and in consequence of the displaced cardiac impulse and the increased area of pulsation, it may appear to be much larger than it really is. When the right lung is affected there may be well-marked epigastric pulsation, and the cardiac impulse may be to the right of the sternum in the fifth intercostal space, the maximum point being in some cases as far out as the right nipple line. When the left lung is affected, the heart may be pulled over towards the left, so that the cardiac impulse is situated in the anterior or even in the mid axillary line. In consequence of the shrinking of the lung more of the anterior surface of the heart will lie in contact with the thoracic wall, and there may be therefore an increased area of visible pulsation in the second, third, or fourth intercostal space. In addition to displacement of the cardiac impulse there is diminution in the size and decrease in the movement of the affected side of the chest, the shoulder is drawn down, the spine curved with the concavity towards the affected side: there is increased tactile vocal fremitus, impairment of note on percussion, and, should there be dilated bronchial tubes, there are cavernous or amphoric breathing, bronchophony, pectoriloquy, and loud crackling râles. With the exception of compensatory emphysema there may be no sign of disease in the other lung, a point which helps to distinguish this condition from phthisis. The chief symptoms are chronic cough, dyspnoea, abundant expectoration, especially on rising in the morning, the sputum often being fetid on account of the bronchiectasis so frequently associated with fibroid lung. The patient may be well nourished and show no signs of loss of flesh. Hemoptysis occurs occasionally, but no tubercle bacilli will be found in the sputum. There is often extreme clubbing of the fingers. When it is the right lung that is fibroid the heart may be drawn so far over to the right side that a mistaken diagnosis of transposition of the heart has sometimes resulted, owing to the fact that the cardiac impulse may seem to be in the right nipple line instead of in the left. If there is doubt in such a case, X-ray examination of the thorax will decide it.

Chronic Bronchitis and Emphysema may so increase the volume of the lungs that they cover the anterior surface of the heart completely: consequently the cardiac impulse may be invisible, the superficial cardiac dullness diminished or absent, and the heart-sounds faint or even inaudible. In these circumstances it is not an easy matter to diagnose enlargement of the heart without the assistance of X-ray examination. Should there be dilatation of the right ventricle as well as hypertrophy, and also tricuspid regurgitation, a systolic murmur may be heard over the lower part of the sternum and in the fourth and fifth left intercostal spaces close to the sternum, and oedema of the legs, ascites, enlargement of the liver, and albuminuria may also be present. If, in addition, there are signs of pulmonary emphysema, viz., the cubical chest, little difference between inspiratory and expiratory circumferences, wide epigastric angle, increased tactile vocal fremitus, hyper-resonant percussion note, diminished area of hepatic and cardiac dullness, increased voice-sounds, diminished vesicular murmur with prolongation of the expiratory sound, with or without non-consonating râles and rhonchi, and if there are no indications of fibrosis of the heart valves from former endocarditis, chronic Bright's disease, or primary arteriosclerosis, enlargement of the heart with failure of compensation as a result of chronic bronchitis and emphysema may be diagnosed.

3. DISEASES OF THE RIGHT SIDE OF THE HEART.

Pulmonary Stenosis (see p. 267).

Pulmonary Incompetence. This lesion may be associated with congenital pulmonary stenosis, or may be due to infective endocarditis (especially gonococcal), but by far the commonest cause is functional incompetence from dilatation of the pulmonary artery and orifice secondary to the high tension produced in the pulmonary circulation by mitral stenosis. It may be difficult to distinguish from aortic regurgitation: the early diastolic bruit of pulmonary incompetence is most audible, however, in the third and fourth left intercostal spaces midway between the left nipple line and the left border of the sternum, whereas in aortic disease the diastolic bruit is usually heard best in the third left space close to the left border of the sternum. The visible pulsation of the superficial arteries, and the collapsing pulse, which are so characteristic of aortic incompetence, are not present

in cases of pulmonary incompetence, and with the latter the bruit is apt to disappear and reappear on different days, owing to the varying degrees to which the pulmonary orifice is distended as the mechanical result of variations in the efficiency of onflow through the stenosed mitral valve.

Herbert French.

ENLARGEMENT OF THE KIDNEY.—(See KIDNEY, ENLARGEMENT OF, p. 437.)

ENLARGEMENT OF THE LIVER.—(See LIVER, ENLARGEMENTS OF THE, p. 461.)

ENLARGEMENT OF THE SALIVARY GLANDS. (See SWELLING OF THE SALIVARY GLANDS, p. 848.)

ENLARGEMENT OF THE SPLEEN.—(See SPLEEN, ENLARGEMENT OF, p. 774.)

ENLARGEMENT OF THE THYROID GLAND.—(See THYROID GLAND ENLARGEMENT, p. 876.)

ENOPHTHALMOS (or Retraction of the Eyeball). This may occur: (1) In wasting diseases; (2) In paralysis of the cervical sympathetic; (3) In various congenital affections.

The enophthalmos in *wasting diseases* is due to the absorption of the orbital fat, and the diagnosis as regards the eye presents no difficulty.

Enophthalmos due to *paralysis of the cervical sympathetic* is always associated with the other well-defined symptoms of this condition, namely, diminution in the size of the palpebral aperture (*Fig. 221*), constriction of the pupil, absence of sweating and blushing

on the paralysed side; occasionally it may be noticed that the hair over half the head on the affected side is behaving differently from that on the sound side—it may lie flatter, or may lack lustre to a degree that the patient observes. The pupil is constricted owing to the paralysis of the dilator fibres, the pupil therefore not dilating in a feeble light.

In certain *congenital cases* there is well-marked retraction associated with defective or irregular movements of the affected eyeball. The ocular muscles are, as a rule, inserted much farther back in the sclerotic than is normally the case. The condition appears to be due to the absence or defective insertion of the extrinsic muscles of the eye, and may be recognized by its existence since birth.

Herbert L. Eason.

Fig. 221.—A case of paralysis of the left cervical sympathetic, showing slight but definite ptosis of the left upper eyelid and enophthalmos of the left eye. The left pupil was smaller than the right. The cause of the paresis was lymphosarcoma of the superior mediastinum.

ENURESIS occurs almost exclusively in children, and although most frequently confined to the night, it may occur in the day. It must be distinguished from incontinence of urine; the patient has usually full control of micturition during the day, although sometimes the desire to urinate must be satisfied quickly or a little dribbling may take place. The child completely empties the bladder, often without waking, once or several times during the

night. The bladder need not be quite filled for micturition to occur, for it usually takes place in the early hours of the night.

Enuresis is often accompanied, and may be caused, by slight affections such as phimosis, balanitis, small urinary meatus, vulvitis, constipation, or intestinal worms, the correction of which remedies the trouble, but in other cases there seems nothing to promote the excitability of the detrusor muscle. It may be present in cases of enlarged tonsils and adenoids, when the enuresis has been attributed to partial asphyxiation. Should enlarged tonsils or adenoids be present, they should be removed before other treatment is ordered. Enuresis in some cases may be due to thyroid deficiency, and good

results may follow the administration of thyroid extract in small doses. It has been stated that the condition is due to faulty development or deficient innervation of the sphincter muscle, or to spasm of the detrusor; but this is difficult to prove. If the sphincter muscle were paralysed or deficient there would be true incontinence of urine, whereas this is not so, and the children are often of good development and health. It is probable that in most cases of simple nocturnal enuresis the cause lies in the fact that the infantile condition in which the detrusor muscle holds the mastery over the sphincter persists, a relative disparity between the innervation of the two sets of muscles allowing the detrusor, which normally is held in check by the sphincter, to overcome the comparatively weak action of the latter. When enuresis persists throughout childhood it may disappear at puberty, when the prostate gland enlarges and strengthens the action of the sphincteric apparatus.

It is important to exclude pyelitis, cystitis, phosphaturia, and oxaluria before a diagnosis of simple enuresis is made. In each case nocturnal micturition may be the chief symptom; microscopical examination of the centrifugalized deposit will detect the pus cells or the excess of calcium oxalate crystals, and a bacteriological examination of a specimen of urine passed directly into a sterile bottle or obtained by a catheter should be made in order to diagnose or exclude coli bacilluria (p. 88).

In many cases no source of irritation, alteration in the urine, or disease of the bladder can be found. The child is nervous and sensitive from a feeling of shame due to ill-advised attempts by the parent to cure the trouble by punishment. In some the enuresis may accompany a minor epileptic attack, in which case there may be longer intervals than is usual in simple enuresis, or there may be a history of epilepsy, insanity, or other nerve trouble in the parent.

R. H. Jocelyn Swan.

EOSINOPHILIA denotes a relative increase in the coarsely granular eosinophil cells of the blood (*Fig. 39*, p. 29); it is determined by preparing blood-films and making a differential leucocyte count. Normally, the coarsely granular eosinophil cells vary from 0 to 2 per cent; the point at which eosinophilia begins is quite arbitrary; but one may say that although it is unusual, under perfectly healthy conditions, to find more than 2 per cent of these cells in the differential count, they should reach 5 per cent or more before the term eosinophilia is applied to the condition. It is probable that some normal people have upwards of 5 per cent of these cells, but beyond this point they are nearly always pathological. One may divide the causes of eosinophilia under main headings as follows:

1. Conditions in which Eosinophilia is slight, inconstant, and of little diagnostic significance:—

Post-febrile states, after:

Scarlet fever	Acute articular rheumatism	Varicella
Pneumonia	Measles	Malaria.

Affections of the bone-marrow:

Splenomedullary leukaemia	Rickets	Osteomalacia.
Sarcoma of bone	Osteomyelitis	

Addison's disease.

From certain chemicals, particularly camphor, sulphuretted hydrogen.

In ovarian maladies.

Gonorrhoea.

During the positive stage of tuberculin reaction.

Some cases of malignant disease, especially when there are metastases—carcinoma, lymphosarcoma.

2. Conditions in which Eosinophilia may be marked:—

a. Spasmodic asthma.

b. Certain skin diseases, more particularly the bullous dermatoses:—

Pemphigus	Dermatitis herpetiformis (Dühring's disease)	Herpes iris, or erythema iris
Erythema bullosum		Herpes gestationis.
	Hydroa	

It is much rarer in other cases of skin disease, but is noted occasionally in psoriasis, eczema, and exceptionally in some other affections of the skin.

c. Certain parasitic affections, particularly :—

Ankylostomum duodenale	Bothriocephalus latus	Filaria sanguinis hominis
Bilharzia haematobia	Tenia solium	Trichina spiralis
	Tenia mediocanellata	Hydatid.

It is much less constant, and indeed generally absent, in cases of :—

Ascaris lumbricoides	Oxyuris vermicularis	Pediculus corporis
Trichocephalus dispar	Pediculus capitis	Acarus scabiei.
	Pediculus pubis	

d. As the result of the administration of emetine hydrochloride injections.

The list above almost speaks for itself, and little discussion is needed. None of the conditions named is necessarily associated with eosinophilia, but the coarsely granular eosinophil cells often reach a figure between 5 and 15 per cent in the differential count in many of the diseases that come under headings (a), (b), and (c), whilst sometimes during paroxysmal asthma they may reach 25, 50, or even more per cent, and they are often over 20 per cent in the severer forms of parasitic disease. The eosinophilia of leukaemia has often had stress laid upon it in text-books, but as a matter of fact, although the coarsely granular eosinophil cells per cubic millimetre of blood may be considerably above the normal along with all the other corpuscles, yet when reduced to percentages in the differential leucocyte count the eosinophil corpuscles seldom number more than 2 or 3 per cent of all the white cells present. There are, however, rare cases of *eosinophil leukaemia* in which, in association with great enlargement of the spleen and great leucocytosis, the preponderant leucocyte in the blood—even up to 60 per cent of the total—is the coarsely granular eosinophil cell, and not the basophil or neutrophil myelocyte.

The value of eosinophilia in discriminating between artificial bleb-formation and a true *bullous dermatosis* is mentioned in the article upon BULLÆ (p. 123).

The difficulty sometimes present in deciding whether in a given case the lesion is primary emphysema and bronchitis, or primary *asthma* succeeded by emphysema and bronchitis, is discussed on page 653; and the value of eosinophilia in discriminating between truly asthmatic cases and those which simulate asthma but are really cardiac, renal, or bronchitic, is there referred to. It should be noted that the eosinophilia is not confined to the blood, being present also in the cells in the sputum; it occurs during the paroxysms of asthma, and disappears rapidly in the intervals.

When a patient is suffering from an obscure form of anaemia, and when the blood at the same time exhibits considerable eosinophilia, the latter may sometimes be the first suggestion that there is a serious *parasitic infection* in the case, and careful examination of the faeces or urine for the parasites themselves or for their ova, with the administration of anthelmintic drugs, may then be resorted to for confirmation of the diagnosis (see PARASITES, INTESTINAL, p. 632). Persons who have been resident in the tropics are more liable to unsuspected infection of this kind than are others.

The treatment of anæmic dysentery with *emetine hydrochloride* injections is not always followed by the development of eosinophilia; but in some cases, when eosinophilia was not present previous to the treatment, the eosinophil corpuscles have risen to 8 per cent after it, and this figure is sometimes exceeded, even 40 per cent having been recorded.

Herbert French.

EPIGASTRIUM, PAIN IN.—(See PAIN IN THE EPIGASTRIUM, p. 536.)

EPIPHORA, or overflow of the tears, may be due to: (1) *Increased secretion*; (2) *The puncta lachrymalia not being in close apposition to the globe*; (3) *Obstruction of the lachrymal canaliculi or duct*.

1. The most familiar cause of epiphora due to increased secretion of tears is the act of *weeping*, in which the flow is due to psychological stimuli. Epiphora may also occur in the lachrymation caused by *conjunctivitis*, *corneal ulcers*, and other inflammatory affections of the eye (p. 285). It may also be due to *coryza*, the onset of *measles*, or to *hay fever*; it is sometimes a troublesome effect of certain drugs, particularly *potassium iodide* and

other iodides, *potassium bromide* and other bromides, *arsenic* and *mercury*, of certain vegetables and plants, notably *onions*, *Primula obconica*, *Rhus toxicodendron* : and sometimes it is a purely functional nervous phenomenon distinct from ordinary weeping or crying neurotic lachrymation.

2. Tears only find their way down the canaliculi by capillary attraction, the puncta lachrymalia being applied closely to the surface of the globe. In *facial paralysis*, owing to the failure of the orbicularis palpebrarum muscle, the lids are no longer braced up against the eye, and the lower lid droops away from the globe. The tears collect in the sulcus thus formed, and run over on to the cheek. The condition is easily diagnosed by the patient's inability to close the eye entirely by voluntary effort. In cases of *chronic marginal blepharitis*, hypertrophy of the lid-edge and conjunctiva results in a slight eversion or ectropion : the punctum lachrymale of the lower lid is no longer in apposition with the eye, and epiphora follows, causing continual moisture of the edge of the lids and aggravation of the original condition. Cicatricial ectropion from *burns*, *injury*, *scleroderma*, or *lupus* of the cheek may also result in epiphora ; and so may severe *proptosis* (see EXOPHTHALMOS, p. 283), resulting from tumours or inflammation at the back of the orbit, or from Graves' disease. In old persons epiphora may occur through the lower lids falling away from the globe owing to the disappearance of fat in the tissues and loss of cutaneous and muscular tone. Epiphora is sometimes caused by a *lachrymal calculus* in the canaliculus formed by dense colonies of streptothrix. The calculi cause a swelling in the neighbourhood of the canaliculus, associated with the discharge of pus from the puncture. They may be mistaken for styes, but do not react to treatment, unless the canaliculus is slit open and the calculi are evacuated.

3. The lachrymal ducts may be obstructed from various causes. *Congenital obstruction* is usually unilateral and is due to a plug or septum of uncanalized epithelium situated in the lower part of the duct : the epiphora is as a rule not evident till the seventh or eighth day, at which period the infant first begins to shed tears, and owing to the super-vention of suppuration in the lachrymal sac the malady may be mistaken for chronic conjunctivitis. The unilateral nature of the affection, and the presence of tears or pus in the sac, are the diagnostic signs, and the obstruction may generally be cured by a single probing of the duct through the dilated but uncut canaliculus. Congenital absence of one or both canaliculi has been recorded. Stenosis of the lachrymal duct may also occur as the result of *catarrhal congestion* of the mucous membrane, or from some organic obstruction due to *cicatriziation* following abscess in the lachrymal sac or necrosis of the bones forming the walls of the duct. The diagnosis is made by syringing through the canaliculi : in catarrhal obstruction fluid can usually be forced into the nose, but in organic stricture it is returned through the other canaliculus : in such cases the stenosis can be relieved by the passage of a probe, after slitting the lower or upper canaliculus, or by one of the various operations for the formation of a permanent direct opening from the lachrymal sac into the nasal cavity.

Eversion of the lachrymal sac for chronic suppuration is always followed by epiphora, but this condition may often be preferable to the discomfort caused by recurrent lachrymal abscess and to the risk of corneal ulcer with hypopyon.

Injury to the duct or canaliculus may cause permanent epiphora. *Herbert L. Eason.*

EPISTAXIS rhinorrhagia, or bleeding from the nose—may be due to local or general causes, or to a combination of both. In many cases it occurs spontaneously and no cause can be indicated.

Local Causes :—

Injury. A blow, fracture of the base of the skull, a foreign body in the nose, operation on the nose, violent coughing, sneezing or nose-blowing, nose-picking.

Ulceration. Traumatic, syphilitic, malignant, tuberculous, leprous.

New Growth. Adenoid growths, polypi, fibroma, angioma, malignant disease.

Varicosity of the Veins of the nasal mucosa : multiple hereditary telangiectases.

Acute Infective Inflammation. Severe catarrh, diphtheria, scarlet fever, influenza.

General Causes :

High Arterial Blood-pressure, such as obtains in granular kidney and chronic renal disease, arteriosclerosis, gout, cirrhosis of the liver, heart disease.

High Venous Blood-pressure in bronchitis, emphysema, dilatation of the right heart : in cerebral congestion, when blood passes from the superior longitudinal sinus by an emissary vein going through the foramen caecum to the nasal mucosa : in 'determination of blood to the head' : in schoolboys and children after taking violent exercise.

Altered Conditions of the Blood. Hemophilia, pernicious anemia, purpura, scurvy, leukemia, chlorosis, jaundice, and the onset of acute specific fevers, particularly enteric, scarlet fever, influenza, and measles.

Alterations in Atmospheric Pressure. Mountaineering, diving, caisson disease.

Epistaxis of Obscure Origin, often attributed to congestion, and occurring : In childhood : at puberty, especially in girls : as the alleged vicarious menstruation : as the result of sexual irritation in either sex : in women at the menopause.

In some cases the blood issues from both nostrils : in the majority, particularly when the cause of the bleeding is local, from one only. Nose-bleeding may occur without any blood coming from the anterior nares : if the patient is lying down, the effused blood runs down the sides or floor of the nose, passing through the posterior nares and entering the nasopharynx : when this occurs, the patient may cough and spit it up, when hamoptysis will be observed : if, on the other hand, he swallows the blood, he may vomit it later, when hamatemesis will take place. In the not uncommon instances in which either of these events occurs from epistaxis, careful inquiry should suffice to make the diagnosis clear : but it should not be forgotten that either hamatemesis or hamoptysis may indicate nothing more serious than an attack of nose-bleeding.

In every case of epistaxis the history of the attack should be gone into carefully. Particular inquiry should be made as to any sort of trauma that might account for it, and also as to the occurrence of previous attacks of nose-bleeding. More important still is a careful examination of the local conditions of the nose, with use of a nasal speculum to dilate the nares, and of a mirror and lamp to secure a good illumination. In many cases the bleeding point can be seen, whether the hemorrhage be arterial or venous, the so-called 'seat of election' of epistaxis being a small and perhaps ulcerated spot on the cartilage of the septum not far from its junction with the ethmoid and vomer. In other instances no such bleeding point can be seen, the blood oozing from the mucous membrane generally. The urine should be tested for albumin, and the arterial blood-pressure measured instrumentally. Whenever the blood comes solely from one nostril the likelihood of the cause being local to that side of the nose is considerable.

Recurrent Epistaxis at irregular intervals is likely to be due to some local cause. For example, a small ulcer on the septum nasi, due perhaps to injury in the first instance, may scab over from time to time but never heal satisfactorily : a comparatively trifling injury, such as that occasioned by blowing the nose, may suffice to detach the scab, epistaxis following. Malignant disease of or about the nose, and also adenoid vegetations, often give rise to repeated nose-bleeding. Epistaxis has been a prominent symptom in the rare hereditary disease in which numerous friable telangiectases appear about the surfaces of the body and on mucous membranes (*Figs.* 299, 300, p. 368).

Considerable aid in diagnosing the probable cause of an epistaxis is afforded by the age of the patient. In *infancy*, the cause is likely to be local injury by a fall, a foreign body, the habit of nose-picking, or syphilitic disease of the nasal bones. In *childhood*, falls and blows on the nose are common, the temptation to insert foreign bodies up the nose still asserts itself, adenoid growths in the nasopharynx are common : and general causes such as heart disease, diseases of the blood, or obscure conditions of local congestion, may exist and account for the onset of epistaxis. About the age of *puberty* nose-bleeding may occur in either sex, and particularly in girls, not only in consequence of the causes enumerated already, but also spontaneously. In the healthy, or apparently healthy, *young adult*, almost any of the list of local and general causes may account for nose-bleeding : diagnosis here must rest upon the results of the examination into the local conditions of the nose, and the general state of the organs of the body. In the *old*, on the other hand, and in middle-aged patients of plethoric habit, high blood-pressure with or without general arterial disease is the most important cause of epistaxis : it may be a natural remedy for the plethora from which such persons suffer, and not infrequently does relieve them from such symptoms as a sense of fullness and congestion of the head, tinnitus aurium, or the appearance of flashes of light or muscae volitantes before the eyes. In

other instances it may serve as a warning, drawing attention to the abnormally high blood-pressure and to the chronic interstitial nephritis or arteriosclerosis that underlies it.

A. J. Jer-Blake.

ERUCTATIONS. (See FLATULENCE, p. 302 ; and HEARTBURN, p. 376.)

ERUPTIONS, BULLOUS, VESICULAR, ETC. (See BULLE, p. 123 ; VESICLES, p. 913 ; etc.)

ERYTHEMA signifies a pathological reddening of the skin from vascular hyperemia, the redness disappearing on pressure, to return when the pressure is removed. There is no strict line at which one can say mere redness of the skin ends and actual erythema begins ; for instance, FLUSHING (p. 303) would hardly merit the term erythema in some cases, though it would in others ; clinically, however, there is seldom difficulty in deciding what is erythema and what is not. It may be local or general, and may be due to many causes, including the following :

1. Drugs :

a. External Applications, including all Rubefacients : —

Alcohol and alcoholic preparations	Croton oil	Paraphenylene compounds
Alkalis	Eucalyptus oil	Petrol
Ammonia	Hair dyes	Poultices
Arnica	Hair lotions	Pyrogallic acid
Cantharides	Iodoform	Radium applications
Capsicum	Mesotan	Strong mercurials
Carbolic acid	Methyl-salicylic acid	Turpentine
Certain soaps	Mineral acids	X-ray dermatitis.
Chrysarobin	Mustard plasters	
	Oil of cade	

b. Medicines taken by the Mouth : —

Antipyrin	Chloral	Pilocarpine
Arsenic	Chloral hydrate	Quinine
Aspirin	Chloralamide	Rhubarb
Atropine	Chlorate of potash	Salicylates
Belladonna	Copaiba	Sandalwood oil
Benzoic acid	Cubebs	Sulphonal
Boric acid	Iodides	Trional
Bromides	Mercury	Valerian
Butyl chloral hydrate	Myrtol	Veronal.

c. Therapeutic Agents injected Hypodermically :

Anti-anthrax serum	Anti-pneumococcus serum	Neosalvarsan
Anti-diphtheritic serum	Anti-streptococcus serum	Normal horse serum
Anti-dysenteric serum	Anti-tetanic serum	Salvarsan
Anti-meningococcus serum	Atoxyl	Sodium cacodylate.
	Peptone	

d. Therapeutic Agents injected per Rectum : —

Soap and water enemata	Other enemata.
------------------------	----------------

2. Erythema Artefactum (Malingering).

3. Irritants affecting Workers at Certain Trades, in which they have to handle or come in contact with erythema-producing substances, such as : —

Aniline dyes	Juice of knot-grass (<i>Polygonum aviculare</i>)	Scents
Bitter orange peelers for jam	Leaves of <i>Primula obconica</i>	Tar products
Fishermen handling jelly-fish, sea-cats, weavers, and other fish	Leaves of <i>Rhus toxicodendron</i>	Trinitrotoluene
	Reed-workers	Turpentine
	Resins	Vanilin
	Satin-wood sawdust	Varnish
		Volatile oils.

4. After Operations sometimes, perhaps the result of the anæsthetic.

5. Extremes of Heat or Cold : —

Erythema solare	Erythema ab igne	Erythema a frigore.
-----------------	------------------	---------------------

6. Around Inflammatory Foci, such as :—

Over any abscess as it nears the surface—appendicular, mastoid, dental, hepatic, axillary, inguinal, a pointing empyema, actinomycosis, and so on.
 Round superficial inflammations of the skin, such as boils, carbuncles, furuncles, malignant pustules, and so on ; or as part of other skin lesions, such as eczema, lupus erythematosus, urticaria, ringworm, tinea versicolor, erythema iris, hydroa, erythema nodosum, phlebitis, cellulitis, lymphangitis.

7. As part of a General Illness, in which the symptoms are likely to be even more prominent :

Cerebrospinal meningitis	Ptomaine poisoning	Dengue
Encephalitis lethargica	Malaria	Lymphadenoma
	Leprosy	Leukæmia.

8. As a Prominent Symptom of a Disease which may or may not present other symptoms at the time :—*a. Localized Erythema* :—

Erysipelas	Erythema induratum (Bazin's disease)	Pellagra
Small-pox	Polymyositis	Meigs's disease
Gout	Trichinosis	Angioneurotic œdema.
Erythromelalgia	Rat-bite fever	
Raynaud's disease		

b. Generalized Erythema :—

Scarlet fever	Acute rheumatism	Filariasis
Measles	Parasitic toxæmias, e.g., from	Trypanosomiasis
German measles	Hydatid disease	Snake bite.
'Fourth' disease	Tapeworm	

9. Generalized Erythema without obvious cause :—

Erythema simplex	Erythema multiforme	Erythema exfoliativum seu scarlatiniforme.
------------------	---------------------	---

In arriving at the cause of erythema in any particular case the diagnosis is often obvious when the possibilities are borne in mind. Indeed, many of the conditions mentioned in the list above do not require any further discussion. The appearance of the part affected will often suggest that some external application is the cause : vesiculation may result from almost any of the substances which, in weaker solution, produce erythema only : there is nothing pathognomonic about the naked-eye appearances from which to tell the application used : the history as to what the patient has been applying to the skin is needed : and if malingering by surreptitious application is suspected the cessation of the lesions when the patient is placed under circumstances where further applications are not possible will confirm this. The red patches produced by carbolic acid may be such as to simulate tinea circinata : but the absence of spores upon the hairs removed from the patch when they are examined microscopically will exclude this.

Local reaction from the application of X rays on repeated occasions is familiar : it differs from X-ray cancer in that, though the erythema may persist for weeks, or may develop into a vesicular eruption (X-ray dermatitis or X-ray burn), which may be very resistant to treatment, it ultimately subsides, leaving a brown pigmented stain, or an area of slowly increasing telangiectasis (*Fig. 222*), whereas X-ray cancer progresses in spite of cessation of the use of the rays, leads to progressive if slow destruction of the affected parts, and ultimately behaves like an ordinary epithelioma.

Radium burns are less common than they used to be, because of greater knowledge of the methods of screening the skin from the effects of the superficial rays by means of lead or silver sheets : but most radium applications are followed by some degree of local reaction, of which erythema is a prominent feature, for a week or ten days, after which the reaction subsides rapidly, though often followed by local brown pigmentation of the skin.

The phenomena of *serum reactions* are familiar : the effects are due to the serum itself rather than to the antitoxin it contains, and they form part of what is known as 'serum disease'. The injection of any foreign protein into the system is followed by chemical reactions in the body antagonistic to the injected protein, and when these reactions are at their height the body is extra-sensitive (anaphylactic) to a further injection of the same

foreign protein. In the case of horse serum this state of anaphylaxis reaches its height about eight or nine days after the original injection : it is at this time that the symptoms of 'serum disease' show themselves clinically. The patient begins to ache all over, with more or less acute pains in the back and limbs, sometimes referred particularly to the joints : headache is usual, and there may be vomiting : the temperature rises moderately, the tongue is coated, and appetite fails : at the same time a blotchy red eruption appears upon the skin, sometimes universally, but generally with maximum intensity round the site of the inoculation. There is intense itching, the patient may not be able to sleep, and may not have enough fingers to scratch himself with. The eruption is sometimes a pure urticaria, but quite as often generalized erythema preponderates, with multiple urticarial wheals amongst the erythema. Vesication is uncommon. These symptoms last but a day in mild cases.

Two, three, or even four days in others. They nearly always subside spontaneously, but in a few instances the serum reaction has been so intense as to prove fatal.

The erythema which sometimes follows the injection of *salvarsan*, *neosalvarsan*, *atoxyl*, *galyl*, *kharsivan*, or *sodium cacodylate* may be severe for a time, but it is usually transient, and it develops in only a small minority of cases. It is probably due to the arsenic which is present in relatively high proportions in organic combination in these drugs.

The erythema that may follow *enemata* is generally universal, and for the time being the patient looks very much as if he had scarlet fever. Indeed, the physician may be unable at the moment to make sure that it is not scarlatina, especially if the case is febrile already. The erythema disappears in about twenty-four hours or less, is not accompanied by vomiting, sore throat, or albuminuria, and is not followed by desquamation. The fact that it has followed directly after the administration of an enema is the main point in the diagnosis.

Erythema due to the various trade causes mentioned under Group 3 in the above list may not be relegated to its correct cause unless the nature of the patient's occupation is fully understood : but a general indication which is common to all this group of erythemata is that the patient does not suffer when he is away from his work, but gets recurrences when he returns to his old surroundings. The same applies to the effects of certain garden and hot-house plants, though here the source of the irritant may escape diagnosis unless the possibility is borne in mind : particularly in the case of persons living in houses upon which *Rhus toxicodendron* is growing in place of ampelopsis as a virginia creeper. *Knot-grass* is a common weed in some districts, but it is not likely to produce

FIG. 222. Telodermatosis of the skin left after an X-ray erythema produced as a result of treatment of recurrent carcinoma of the supraclavicular glands in a case in which carcinoma of the breast had been removed four years previously.

erythema unless the patient has recently been indulging in extensive weeding operations in the garden. *Primula obconica* in the greenhouse is a plant that causes extreme dermatitis in susceptible individuals, others being immune.

The stings of *jelly-fish* are familiar to bathers as well as to fishermen, and in addition to intense itching and irritation, acute oedema may result and generalized erythema and urticaria. The skin eruption may not be confined to the part actually stung by the jelly-fish, for sometimes after a latent period of from twelve to twenty-four hours there may be a generalized erythematous eruption although the jelly-fish sting may have been purely local. It is not so much the small, flat, gelatinous jelly-fish that are the worst offenders in this respect, as the much larger ones with long red streamers.

The effects of being pricked by the spines on the gills or fins of certain fish, especially *sea-cats* and *weever fish*, are familiar to most fishermen: in addition to acute irritation of the skin, with or without urticaria, there may be intense swelling, vomiting, headache, and a feeling of such illness that the patient may be confined to bed in a temporarily serious condition for several days. Sometimes, indeed, the local spot which has been pricked may fester and remain a sore for many months.

Most of the trade irritants are apt to go further than the production of erythema, an acute vesicular dermatitis being even commoner as the result of irritants mentioned on page 275.

Little need be said about the erythema following upon *operations*, or that which follows upon *extremes of heat or cold*. Local erythema, especially of the feet, was very common amongst those who had to man the trenches in the great war: in most instances it stopped short of actual frostbite with gangrene, but the erythema persisted for weeks or months, accompanied by swelling and great local pain and consequent limping gait.

One need not discuss from the point of view of the erythema itself the reddening that may be associated with abscess formation, phlebitis, cellulitis, lymphangitis, etc., mentioned in Group 6 in the above list. The diagnosis is indicated by other symptoms that will be present.

Ptomaine poisoning is characterized much more by acute vomiting, accompanied or followed by severe recurrent diarrhoea, than it is by erythema: but in some cases in which erythema is a prominent feature it may make the diagnosis less easy than when it is absent. When a single patient is attacked the nature of the condition may be difficult to determine unless inquiry into the previous dietary shows that some particular food likely to produce ptomaine poisoning has been partaken of: the erythema generally comes on either at once or else twenty-four hours or more after the food in question. It is noteworthy that precisely similar erythema may result in some cases from the ingestion of foods which do not make other persons ill at all, in which respect there are personal idiosyncrasies to crab, strawberries, and occasionally to other quite ordinary foods which the patient can never take without suffering from erythema or urticaria, or both.

In *cerebrospinal meningitis* and in *encephalitis lethargica* generalized erythema is only one of many possible skin eruptions: herpes facialis is much commoner, and a vesicular eruption on the trunk and limbs is more usual than one which is purely erythematous. Most characteristic of all, however, are purpuric spots, varying in size from mere petechiae to relatively large purple blotches, though this purpura develops in less than half the cases: at the same time there will in most cases be somnolence, headache, green vomit, and pyrexia to indicate the nature of the malady, the diagnosis of which is confirmed by finding meningococci after lumbar puncture. Sometimes the skin eruption simulates measles so closely that the latter is diagnosed in error until post-mortem histological examination of the mid-brain has been made.

In *malaria* acute erythema is not common: the patient will generally give a characteristic history of recurrent rigors with intervals of perfect health, and he will have lived or be living in a malarial district: hæmatozoa (*Figs. 57-60*, pp. 40-41) will be looked for in the blood.

Leprosy is discussed on page 501, and *dengue* on page 571: patchy erythema is almost constant in the latter, but is not so frequent in the former.

The main characters of each of the various diseases that may be associated with localized erythema mentioned in Group 8 (*a*) in the list above, are described in other parts of this volume: *erysipelas* on page 824; *small-pox* on page 684; *erythromelalgia* on

page 320 : *Raynaud's disease* on page 320 : *erythema induratum*, or Bazin's disease, on page 502 : *polymyositis* and *trichinosis* on page 569 : and *rat-bite fever* on page 740.

Pellagra, rare though it is in this country, has now been recognized in so many individual patients and in such various parts of Great Britain, that it merits special mention, for although it is much commoner in other countries, especially Italy, it seems likely that it would be diagnosed correctly, and more often, if its chief characters were more familiar. The malady is one of months or years as a rule, and a certain proportion of the cases recover. The disease usually starts with acute gastro-intestinal disturbances in the form of nausea, vomiting, and diarrhœa, which last is generally severe and sometimes intractable. Acute ptomaine poisoning may be simulated at this stage : but the diarrhœa, which is seldom absent, persists in a way that will exclude ptomaine poisoning, whilst at the same time there is generally a remarkable soreness of the mouth and tongue and considerable salivation, such as does not accompany ptomaine poisoning. Such an attack may subside, to recur after an interval of days or weeks, and sooner or later nervous symptoms of a serious nature are added. These nerve symptoms may take the form simply of progressive weakness, but more often they may simulate some gross intracranial change, on account of the severity of headache with vomiting and giddiness, semi-coma, and even, in exceptional cases, optic neuritis or optic atrophy. Hallucinations are common, and not a few of the patients become actually insane, though this does not happen as a rule until the disease has been present for some time. During exacerbations there may be pyrexia, sometimes of long duration (*Fig. 223*), though generally not of severe degree.

Fig. 223. Temperature chart of the last five weeks of an exacerbation of pellagra in a case which occurred in the south of Lancashire. The patient had been ill, with fever, for seven weeks before he was admitted to hospital.

The two chief groups of symptoms which call attention to the seriousness of the patient's illness in its earlier stages are the gastro-intestinal on the one hand, and the cerebral upon the other. If either of these were present alone the correct diagnosis would probably never strike one, but the characteristic feature which may very likely call one's attention to the nature of the case, rare though the condition is, are the changes in the skin. A few days, weeks, or months after the first onset there develops on the backs of the hands a remarkable discoloration which, at first red and erythematous, presently becomes more pigmented, so as to resemble a condition of extreme sunburn. The skin soon becomes not only dark but thickened and rough, and presently cracks or fissures occur and desquamation follows. Such an attack of erythema of the dorsal surface of the hands may subside, to recur again after an interval, and it may then spread to the face or other parts, remaining nearly always symmetrical (*Fig. 224*). There is a well-defined line of demarcation between the erythematous or pigmented parts and the normal skin immediately above it. It is by these skin changes that the disease is recognized, and it is generally upon looking back over the history that one realizes that the previous cerebral or gastro-intestinal attacks were part of the same malady. Cases have been recorded in patients who have never been out of London, whilst in some village districts in Hampshire and in some parts of Scotland several consecutive cases have been recognized in the same valley, and there is a belief, not yet proved, that the disease is microbic, and spread by infection from water derived from particular soil : though there is an alternative theory that it is a malady of diet, pellagra having been attributed to maize in much the same way that beri-beri is to decorticated rice.

Both *Meigs's disease* and *angioneurotic œdema* are characterized by œdema rather than by erythema in the great majority of cases (p. 512) : in each of these two conditions, however, which are doubtless in their primary pathology related to one another, both being

functional disorders of the vasomotor system, the patient is liable to acute attacks associated with vomiting, possibly diarrhoea, malaise, generalized backache and limb pains, pyrexia up to 101° or 102° F., and acute erythematous eruptions which may be localized or general. The erythema is very similar to that of erysipelas, especially when the attack is localized, and it is more than probable that when the first attack occurs erysipelas will be diagnosed. The attack may last a day or two, or a week, and then subside either completely, or, in Meige's disease particularly, there may be a temporary or even permanent increase in the localized oedema. The exact nature of such attacks may escape recognition

Fig. 224. (This patient had a severe attack of pellagra during the summer of 1919, and went into complete remission in about two months. He has not come under observation since. Note lesions on hands, lower part of forehead, forehead, side of nose, and chin. (By Dr. Frederick R. Tucker, U.S.A.)

until familiarity is established by their recurrence in the same patient at intervals of months or years, each subsequent attack being very similar to the one before; another point which may assist the diagnosis even in a first attack is the occurrence of similar pyrexial and erythematous bouts in other members of the same family, for both Meige's disease and angioneurotic oedema are familial disorders.

The erythemata due to parasitic toxæmia, especially to *hydatid disease*, *tapeworm infection*, *filariasis*, and *trypanosomiasis*, may sometimes be extreme, and in a case of severe erythema with constitutional symptoms in which no apparent cause can be found, examination of the faeces for tapeworm ova should not be omitted. In some cases of hydatid disease generalized erythema has been the first symptom to draw attention to the fact that anything was wrong, but to attribute such erythema to hydatid infection would be exceedingly difficult unless upon physical examination some evidence of a cyst in the liver, in the peritoneum, or elsewhere could be found. If the possibility were suspected, but no confirmatory signs discovered, an additional test is the specific hydatid serum reaction, for which blood can be taken from the patient, as in testing the Wassermann reaction, and sent to a special laboratory for examination. If there were acute erythema from hydatid disease, the hydatid would almost certainly be active and the patient's blood serum would give a positive hydatid precipitin

reaction; whilst *EOSINOPHILIA* (p. 271) would probably be pronounced also. The erythema of filariasis and of trypanosomiasis may occur early in the affection; the nature of the malady would be proved by the discovery of filaria embryos (*Fig. 603*, p. 779) or of trypanosomes (*Fig. 604*, p. 779) in the patient's blood, though the nature of the infection would first be suggested by the history of residence in countries in which one or other of these parasites is prevalent.

There remain for discussion *erythema simplex*, *erythema multiforme*, *erythema exfoliativum seu scarlatiniforme*, scarlet fever, German measles, 'fourth' disease, and the erythema of acute rheumatism. When erythema due to any of these causes is met with the main object in the diagnosis will be either to recognize or to exclude *scarlet fever*.

It will be found in practice that it is sometimes quite impossible to be certain whether a given generalized erythema is that of scarlet fever or not. So much a matter of opinion may it be that even at a consultation between the highest physicians some will consider the lesion to be that of scarlet fever, others will say that in their opinion it is certainly not scarlet fever. The importance of the decision lies in deciding whether the patient should be sent to a fever hospital or not. If the condition is not scarlet fever, then by so sending the patient to a fever hospital one renders him liable to get scarlatina if his erythema is of some other kind. If, on the other hand, his condition is really one of scarlet fever, and it is regarded as non-scarlatinal from the atypical character of the rash, other individuals in the household or community may catch the infection if the patient is treated as suffering from some other form of erythema. The right thing to do under such circumstances is to isolate the patient as though it might be scarlet fever, until the progress of the case and other circumstances prove that it is not; carrying out the isolation in a separate room, in which the patient himself runs no risk of infection from proved scarlatinal cases. In not a few such instances there will be doubt for all time as to whether the patient has had scarlet fever or not; because, especially nowadays, the scarlatinal rash is sometimes almost transient and is often atypical. The important points to pay attention to are: the onset of the illness on the day before the rash appears, with vomiting as an early symptom; the extreme redness of the throat, fauces, and pharynx; the coated tongue, perhaps with red fungiform papillae projecting through the pallor of the fur; pyrexia of 102° or 103° F. which if the case be followed should fall by lysis and reach normal about the end of the first week if there are no complications such as otorrhoea or adenitis; tender swellings in the neck; absence of all rash upon the face, forehead, scalp, or behind the ears, associated with a bright scarlet erythematous eruption all over the trunk and limbs, beginning at the root of the neck and extending thence downwards. This erythematous eruption will be found on careful inspection to be not purely erythematous, but an erythema associated with very fine red dots, which show up best if some affected part of the skin is pressed gently with a glass spatula or microscope slide, so that after the redness of the erythema has disappeared by the compression the minute red dots can still be seen. It is a 'punctate' erythema. If with these characteristics the patient also has a mild degree of albuminuria, the diagnosis of scarlatina is exceedingly likely; and if after ten days or a fortnight the characteristic peeling develops, starting round small pin-prick-like foci and extending thence concentrically away from the central minute hole, the diagnosis is almost certain. Upon the hands and feet the desquamation does not have this pin-hole type, the surface epidermis coming off rather in flakes or casts than in fine scales.

One of the most difficult skin affections to distinguish from true scarlatina is *erythema scarlatiniforme*, which has also been called *erythema exfoliativum*; with this, either at the same time that the rash appears, or a few hours before it, the patient becomes suddenly ill, with shivering and loss of appetite, and there may be reddening of the tonsils and fauces, and a condition of tongue very like the strawberry tongue of scarlet fever, with pyrexia. *Erythema scarlatiniforme* is apt to recur in the same patient, and the difficulty of diagnosis will be much less after a second or later attack than it is in a first, but most cases are diagnosed as scarlet fever in their first attack. Owing to the close resemblance between the two diseases it is certainly right that such patients should be isolated in any case. Two points of distinction between the two that are worthy of special note are: first, that with scarlet fever the desquamation seldom begins before the end of the first week and is usually not at all marked until even later than this; in *erythema scarlatiniforme* desquamation, which may be extreme, generally starts whilst the erythema is still present, often on the second or third day, and nearly always not later than the third or fourth; and secondly, that the erythema of scarlet fever may last twelve hours or less, and seldom has a duration of as much as a week, whilst that of *erythema scarlatiniforme* may persist for two or three weeks, or in some cases even for a month or more.

Erythema multiforme, which is one of the erythemata which may be classed as apparently idiopathic, seeing that no cause is known, is generally distinguished from other forms by the fact that it is very seldom purely erythematous. There are nearly always vesicles or even bullae at the same time, whilst scarlet fever and the other erythemata we are discussing practically never become vesicular.

Erythema simplex, which may also resemble mild scarlet fever, or be mistaken for it,

is perhaps even more liable to be mistaken for mild erysipelas : it is seldom universal : much more often it occurs in local patches. If there are several patches on different parts of the body at the same time, erysipelas would be unlikely, nor is the edge of each red patch as much raised or as sharply defined as is that of erysipelas : in addition to which there are few if any constitutional symptoms, and little or no pyrexia. Sometimes the patches come and go over a period of days or weeks, either in the same or in different parts of the body, and then the term *erythema fugax* is applied. The diagnosis of erythema simplex can only be made when the circumstances of the case lead one to exclude all other possibilities, and the main difficulty will be to be certain that the patient is not having a very

Fig. 225.—Rheumatic nodules over the knees.

mild and atypical attack of scarlet fever. In all such cases very careful watch should be kept upon the condition of the urine, lest there should be nephritis, really of scarlatinal origin, which if not looked for in this way may escape detection altogether, the patient coming under observation ten or fifteen years later with a Rose-Bradford kidney (p. 14) arising out of a condition which was so mild as to be diagnosed erythema simplex when it was really scarlatina.

Acute rheumatism is liable to be associated with various skin eruptions, including not only subcutaneous nodules (Figs. 225, 226 : and p. 502) and erythema nodosum (p. 502), but also generalized erythema. Doubt has been expressed as to whether some of the cases in which joint pains, transient bruits, and erythema have been attributed to acute rheumatism are really rheumatic at all : but in the absence of proof to the contrary one must in the meanwhile

allow that the older teaching may be correct, and that acute generalized erythema closely simulating scarlet fever may be associated with rheumatic fever. If there are no joint pains in such a case the diagnosis will be very difficult, but if there are joint pains and pyrexia, and if both the pyrexia and the joint pains disappear within thirty-six or forty-eight hours after the administration of salicylate of sodium in appropriate doses, the erythema itself is of little moment in such cases : the main point in the case is to eliminate the possibility of scarlet fever with joint pains, and if there is doubt it will be better to treat the patient as a possible case of scarlet fever than to assume too readily that the condition is rheumatic. Sore throat may be a marked feature in either case.

This leaves for discussion *measles*, *German measles*, and *'fourth' disease*. Both measles and German measles are nearly always maculo-papular rather than purely erythematous as regards the skin eruption.

In the rash in both these diseases affects the face and the neck as much as, and even sooner than, the body or limbs : whereas in scarlet fever the actual exanthem does not attack the face at all, though the latter often has a characteristic appearance of pinkness of the cheeks with pallor round the nose and mouth, the general tone and appearance having been described as the 'peach-blossom' facies. In measles, moreover, there will almost certainly have been some constitutional symptom for about three days before the rash appears, especially running at the eyes and nose simulating a common cold : in addition to which a very helpful point in differential diagnosis is the development of Koplik's spots (Fig. 190, p. 224) within the mouth. These may occur singly, but more often they are in groups varying in number from two or three to a score or more, each spot having a pale, almost white, centre, the size of a small pin's head, surrounded by a deep-red injected periphery : they are to be expected upon the inner surface of the cheeks, upon the mucous surface of the lips, and sometimes upon the gums.

Fig. 226.—Rheumatic nodules over the scapular and shoulder.

generally at some little distance from the teeth. They may also develop upon the mucous membrane of the soft or hard palate, though here they may be simulated by particles of milk if care is not taken to see whether or not they are removable by means of a soft brush.

German measles is more apt to simulate scarlet fever than ordinary measles is, and with German measles there are no Koplik's spots to help one. The rash, however, if inspected carefully in different parts, will generally be found to be a characteristic macular one somewhere, and it will be found upon the face or forehead, or behind the ears, which will not be the case with scarlet fever. The constitutional symptoms are generally slight even though the rash is very extensive, and a very helpful point in diagnosis is the presence in German measles of generalized enlargement of the lymphatic glands, including not only those in the neck, axillæ, and groins, but also those in the occipital region. In scarlet fever, although the glands in the neck may be swollen and very tender, those in the occipital region and elsewhere are not generally enlarged.

The chief remaining difficulty is in connection with what has been called '*fourth disease*'. Though this is accepted by many observers as being a distinct entity, its existence is not allowed by all. It has struck many observers, however, that patients who have been known to have had German measles and ordinary measles and scarlet fever definitely in the past, may yet develop an acute erythematous exanthem which has some of the characteristics of measles, some of the characters of German measles, and some of the characters of scarlet fever, without, however, being typical of any one of these three. The malady may spread through a school or a household or institution, and produce similar characteristics in other individuals who, not having had scarlet fever or measles before, if seen by themselves would be diagnosed as suffering from one or other of the three better-known maladies. As, however, in such an epidemic it may attack those who have had scarlet fever before and also those who have had measles before and those who have had German measles previously, in addition to those who have had all three before, those who have had most to do with cases of this kind incline to the belief that there is a definite '*fourth disease*' distinct from the other three. It is a relatively mild malady, with some pyrexia and some constitutional disturbance, but not much of either, and in all cases there is a widespread erythematous or maculo-erythematous eruption. There are no points which are distinctive of the malady, however, and if it exists at all it can only be diagnosed when circumstances suggest that patients are suffering from it who ought not to be liable to any one of the three better-known exanthems of similar type. The weak point in the argument is that it is a well-known fact that although German measles, measles, and scarlet fever protect against subsequent attacks of the same maladies in most individuals, there are some who may have not only two but three or even several separate attacks of German measles, measles, or scarlet fever, and it is on this account that one cannot say definitely that there is such a disease at all as the '*fourth disease*'. Hence its diagnosis in any particular instance must necessarily be one of opinion only.

ERYTHRÆMIA. (See POLYCYTHÆMIA, p. 650.)

ERYTHRASMA. (See FUNGUS AFFECTIONS OF THE SKIN, p. 309.)

ERYTHROPSIA. (See VISION, DEFECTS OF, p. 920.)

EXOPHTHALMOS (or Proptosis). This may be bilateral or unilateral.

Bilateral Exophthalmos. The commonest cause of this condition is *Graves' disease*, in which the exophthalmos is associated with other general symptoms, such as tachycardia, swelling of the thyroid gland, fine tremors, and general nervousness. The eyes are pushed forward to a varying extent (*Fig. 247*, p. 292), in some cases the protrusion being so great that they cannot any longer be covered entirely by the lids. The protrusion causes the upper lid to be unusually raised, and the eyes look wide open, giving the patient an expression of alarm or astonishment (Stellwag's sign, due to spasm of the levator palpebræ superioris). When the eyes are lowered, the upper lids do not descend to the same extent as the cornea, but leave a broad portion of the sclerotic visible above the cornea (Von Graefe's sign). Winking takes place less frequently, and convergence of the eyes is sometimes rendered difficult (the sign of Moebius).

Bilateral exophthalmos may also be caused by *thrombosis of the cavernous sinuses*.

This condition is usually secondary to some furuncle or carbuncle of the skin of the face in the region of the eye, to orbital cellulitis, or suppuration in the accessory sinuses of the nose. It usually starts on one side, and invariably spreads to both in the later stages of the attack. The eyes are protruded and fixed, the eyelids are red and engorged, and the frontal and ophthalmic veins are dilated and full. Movements of the eyes are very limited, and there is much swelling and induration of the orbital tissues. In association with the orbital infiltration there is often some swelling in the region of the mastoid process, owing to the exit in this region of an emissary vein in connection with the sinuses that communicate with the two cavernous sinuses. This condition is nearly always fatal, as it is followed by a suppurative meningitis.

Unilateral Exophthalmos may be due to:—

Orbital cellulitis	Meningocele and encephalocele	Tubercle
Thrombosis of the cavernous sinus	Gumma	Arteriovenous aneurysm
Orbital periostitis	New growth	Distention of the accessory sinuses of the nose.
	Exostosis	

The diagnosis of *orbital cellulitis* and *thrombosis of the cavernous sinus* presents little difficulty, owing to the symptoms of acute inflammation that are present, orbital cellulitis being distinguished from cavernous sinus thrombosis by the fact that it is usually unilateral and there is no oedema in the mastoid region.

Orbital periostitis, especially in more chronic cases, may give rise to varying degrees of proptosis, and in the absence of any obvious thickening of the orbital margins the diagnosis may be obscure. In any periosteal inflammation of long standing a skiagram will usually show a definite increase of density in the affected bone.

Meningoceles and *encephaloceles* may in some cases be difficult to diagnose from dermoid cysts. The latter are usually placed anteriorly in the orbit, and do not therefore

cause any proptosis, though they may displace the eyeball. A meningocele usually presents itself through a gap between the ethmoid and the frontal bones, and is attached to the bone. An opening may sometimes be found through which the meningocele communicates with the cranial cavity. Meningoceles sometimes pulsate in association with the arterial and respiratory oscillations. They may also be diminished in size by pressure of the fingers, as the fluid can be squeezed into the cranial cavity. In many cases an exploratory puncture is the only means of making a certain diagnosis.

A *gumma* of the orbit can only be diagnosed from the patient's general history, evidence of specific disease elsewhere, a positive Wassermann's serum reaction, and improvement in the condition after the administration of salvarsan, mercury, or iodide of potassium.

A *growth of the orbit* (Fig. 227) has usually no distinctive feature, the exact nature of the trouble

Fig. 227.—Unilateral exophthalmos due to lympho-sarcomatous deposits in the left orbit.

being verified as a rule by an exploratory operation and the removal of a portion for microscopical examination: but it may be noted that tumours of the optic nerve can usually be diagnosed with accuracy by the fact that they always produce some compression of the eyeball in the anteroposterior diameter. Cases of proptosis, therefore, in which there is increasing hypermetropia on the affected side, may be ascribed to a primary tumour of the optic nerve.

Ivory exostoses or *osteomata* usually arise from the frontal bone and are attached by a broad base, so that their removal presents very great difficulty: the diagnosis depends on their slow growth and excessive hardness: a skiagram shows their presence with some certainty.

Some cases of *tuberculous disease of the orbit* may closely simulate orbital cellulitis or distention of the accessory sinuses of the nose, and the diagnosis can only be made with

certainly after excision of a portion of the infiltrated tissue and a microscopical examination of the fragment.

An *arterial aneurysm* is nearly always associated with a pulsating exophthalmos, in which there is protrusion of the eyeball and dilatation of the blood-vessels of the retina, lids, and conjunctiva. There is distinct pulsation of the eyeball and a loud blowing murmur on examination with the stethoscope. Compression of the carotid on the same side diminishes the pulsation and the sound. The usual cause of arterial aneurysm is the rupture of the carotid into the cavernous sinus as the result of an injury.

Rare cases are also seen of intermittent exophthalmos, which appears only at intervals or when the head is depressed: these are usually due to *varicose veins in the orbit* not in communication with an artery.

The protrusion of the eyeball due to *dilatation of the accessory sinuses* of the nose is, as a rule, less an exophthalmos than a displacement of the eyeball downwards and outwards. A frontal sinus dilatation causes a displacement a little forward and much downwards and outwards. Ethmoidal and sphenoidal dilatation cause more proptosis than lateral displacement. With dilatation of the frontal sinus there may be some thickening and fullness of the supra-orbital ridge associated with pain and tenderness over the eyebrow: with dilatation of the ethmoidal cells there is usually a definite swelling to be felt at the inner side of the orbit, which is compressible though not distinctly fluid: dilatation of the sphenoidal sinus is sometimes accompanied by neuritis or atrophy of the optic nerve: in all cases of proptosis due to sinus trouble of any duration there is evidence in the nose of inflammation of these cavities, the usual symptom being the existence of polypi or of definite swellings in the region of the infundibulum.

A *growth of the superior maxilla* causes a displacement of the eye upwards.

Suppuration in the maxillary antrum very rarely causes proptosis or displacement of the eye.

Herbert L. Eason.

EXTENSOR PLANTAR REFLEX. (See BABINSKI'S SIGN, p. 87.)

EYE, ACUTE INFLAMMATION OF (*Figs. 228-237*). Acute inflammation of the eye may be due to three main types of disease, *conjunctivitis*, *iritis*, and *glaucoma*. The character of the inflammation varies with the type of the disease, but certain symptoms, such as *pain*, *photophobia* (intolerance of light), and *lacrimation*, are common to all inflammatory conditions, and are therefore by themselves of little value in differential diagnosis.

Conjunctivitis. In conjunctivitis the conjunctival vessels are dilated, bright red, and injected: they are freely movable over the subjacent sclerotic, and the injection is most evident in the equatorial region of the ball of the eye, the circumcorneal portion of the conjunctiva, owing to its firmer attachment to the sclerotic in this region, being relatively paler. The cornea is usually clear and polished, unless there are corneal ulcers: the anterior chamber and iris are normal in appearance, the pupil is black, and the iris active. Purulent material collects at the inner angle of the palpebral aperture and on the edge of the lids, especially after sleep: there is often a feeling of grittiness as of sand or dust in the eye, owing to oedema of the inner surface of the lids and enlargement of the lymphoid follicles in them.

In the ordinary *infectious* or *catarrhal* ophthalmia ('pink eye') the inner conjunctival surface of the lids is velvety and swollen, but there is little or no oedema of the conjunctiva covering the eyeball. In *gonorrhoeal conjunctivitis* by contrast, a brawny oedema of the lids and intense swelling and oedema of the conjunctiva, which is raised all round the cornesclerotic margin (*chemosis*), is a prominent symptom. In the earlier stages of the infection the discharge is yellow, serous, and blood-stained, but it rapidly becomes purulent and extremely profuse. The cornea ulcerates as a rule, its substance apparently melting away in a characteristic manner. Gonorrhoeal ophthalmia of the newborn (*ophthalmia neonatorum*) exhibits similar symptoms, early and destructive ulceration of the cornea and subsequent blindness being one of its most serious complications. In *follicular conjunctivitis* the conjunctiva, especially of the lower lids, is studded with small raised lymphoid follicles, which look transparent and gelatinous. In *trachoma* the conjunctiva

is also studded with enlarged follicles, but in this disease they are found particularly on the under surface of the upper lid and in the upper conjunctival fornix. The follicular enlargement is associated with considerable thickening and oedema of the tissues of the upper lid causing a partial ptosis, with profuse lachrymation, and, in the later stages, with a vascular opacity (*pannus*) of that part of the cornea which is usually covered by the upper lid; in the later stages of trachoma the infiltration is followed by the formation of

Fig. 228. Acute conjunctivitis.

Fig. 229. Acute iritis.

fibrous tissue, causing bending of the tarsal fibrocartilage, entropion, and trichiasis. In *phlyctenular conjunctivitis* there are to be seen one or more round yellowish raised masses at the corneosclerotic margin surrounded by a localized area of vascular conjunctiva. In some cases the phlyctenules may encroach upon the corneal surface, being followed by a trail or leash of conjunctival vessels. *Chronic conjunctivitis* in adults is sometimes characterized by being confined to the inner and outer angles of the palpebral aperture

Fig. 230. Phlyctenular conjunctivitis.

Fig. 231. Follicular conjunctivitis.

(angular conjunctivitis), the infection being due in this case to the diplobacillus of Moran-Axenfeld; in this form of conjunctivitis the edges of the lids as well as the conjunctiva are moist and red, especially at the inner and outer canthus.

In *membranous conjunctivitis*, which may be due either to the diphtheria bacillus or more commonly to staphylococci, the under surface of the lids is covered with a yellowish-white membrane which can be peeled off, leaving a raw bleeding surface.

Corneal ulcers are always apparent as greyish or white opacities of the cornea over which the cornea has lost its polish. There may be only infiltration of the cornea, or in more serious cases actual loss of substance, which may ultimately lead to perforation of the cornea. In certain cases of corneal ulcer there may be pus in the anterior chamber (hypopyon). The diagnosis presents no difficulty; the ulcers are obvious if the cornea be examined carefully.

Fig. 232. Chronic blepharitis.

Fig. 233. Interstitial keratitis.

Iritis. In iritis the inflammation of the eye presents rather different characteristics, for the iris receives its blood-supply from the deeper ciliary vessels, and the dilatation of these shows a marked contrast to that of the conjunctival vessels. The injection is most evident in the circumcorneal region, the equatorial region of the eyeball being paler, and the colour of the injection is not bright red but of a dusky or even violet character. The cornea retains its polish, but the aqueous is usually turbid, and there may be actual

Fig. 234. Hypopyon and ulcer of the cornea.

Fig. 235. Subconjunctival hemorrhage from injury.

punctate deposit of fibrin and leucocytes on the posterior surface of the cornea (*keratitis punctata*) or a deposit of pus at the lower part of the anterior chamber between the cornea and the iris (*hypopyon*).

Owing to the increased vascularity of the iris, and to the exudation into its substance, its volume is increased and its mobility impaired; hence the pupil is small and sluggish or inactive. The presence of blood and exudate in the substance of the iris also changes its

colour—a blue iris becoming greenish, and the fine detail of the iris structure is blurred and obliterated. In the later stages *adhesions* are apt to occur between the iris and the lens at the point of their immediate contact, the edge of the pupil; in the constricted state of the pupil these may not be seen, but on dilatation with atropine these adhesions or *posterior synechiae* prevent the enlargement of the pupil at certain points, and it therefore becomes irregular in shape: small masses of iris pigment may also be seen on the anterior surface of the lens where the mydriatic may have broken down some of the weaker adhesions. Lymph may be exuded into the pupillary aperture, where it will be recognized as a filmy grey membrane completely or partially blocking the pupil.

Glaucoma. Inflammatory glaucoma is an acute disease of the later years of life, attacking women more frequently than men, hypermetropes rather than myopes, and especially those who use their eyes for close work to a considerable extent. It comes on in bouts, often precipitated by ocular strain or indiscretions of diet or regimen. It may affect one eye only at first, but later both eyes are usually attacked.

At first the chief complaint is of attacks of temporary obscuration of vision, the appearance of halos or rainbows round lights, and unusually rapid increase of presbyopia, or failure of accommodation for near vision. During a mild attack there is often a feeling of tension in the eyes and a dull frontal headache in addition to the loss of vision. In severe attacks the pain is violent, radiating from the eye to the head, the ears, and the

Fig. 236.—Glaucoma.

Fig. 237.—Trachoma.

th, and is associated with sickness, the latter symptom often causing the condition to be mistaken for migraine or sick headache. The lids may be oedematous and the conjunctiva injected. The cornea is hazy and anæsthetic, the anterior chamber is shallow, the iris discoloured, and the pupil dilated and fixed. The eye is hard to the touch and very tender. Vision fails rapidly, diminishing in a few hours from normal to the bare perception of light. In the acute stages the optic disc is not visible owing to the opacity of the cornea, aqueous, and vitreous; but ultimately, when the media clear, the optic disc will be seen to be white and excavated (Fig. 428, p. 520).

Subacute or simple glaucoma, but for its slower course and the absence of severe attacks, resembles acute glaucoma. The first evidence of failing vision in chronic glaucoma is, as a rule, the presence of elongated enlargements of the normal blind spot: these blind areas bend over towards and sometimes surround the centre of the field of vision, forming paracentral or annular scotomata; in the later stages the nasal field of vision is nearly always extensively restricted, while the temporal field is unaffected: in some cases of chronic glaucoma there is a pronounced concentric limitation of the field of vision.

The importance of discriminating between iritis and glaucoma cannot be over-emphasized: the use of atropine or some similar mydriatic is the *sine qua non* of the treatment of iritis, whilst in glaucoma it is disastrous.

The points which serve to differentiate these three conditions from one another are summarized in tabular form below :

A SUMMARY OF THE POINTS OF DISTINCTION BETWEEN CONJUNCTIVITIS,
IRITIS, AND GLAUCOMA.

	CONJUNCTIVITIS	IRITIS	GLAUCOMA
<i>Conjunctiva</i>	Conjunctival vessels bright red and injected ; movable over subjacent sclerotic ; injection most marked away from corneo-sclerotic margin ; colour fades on pressure	Ciliary vessels injected, deep-red or bluish-red ; most marked at corneo-sclerotic margin ; colour does not fade on pressure	Both conjunctival and ciliary vessels injected
<i>Cornea</i>	Clear, sensitive	Clear, sensitive	Steamy, hazy, insensitive
<i>Anterior chamber</i>	Clear ; normal depth	Aqueous turbid ; anterior chamber slightly shallow	Very shallow
<i>Iris</i>	Normal colour	Injected, swollen, adherent to lens, and muddy coloured	Injected
<i>Pupil</i>	Black, active	May be filled with lymph, small, fixed	Dilated, fixed, rather green
<i>Intra-ocular tension</i>	Normal	Normal	Raised

FACIAL PARALYSIS. (See PARALYSIS, FACIAL, p. 602.)

FACIES, ABNORMALITIES OF. The study of the face in health and disease, while it cannot replace careful systematic examination of the body as a whole, may in many cases direct the experienced observer's attention to the most likely field in which to find data for his diagnosis. Observation and experience alone can teach the student to detect all that is to be learned from the patient's facies. Photographs and drawings can only illustrate the coarse and obvious defects which are present when the face is at rest or when some particular movement is being sustained. The more subtle abnormalities of expression, the play of the emotions, and the response of the features to intelligence, are often too fleeting and too mobile to allow of reproduction on paper, and sometimes so intangible as to defy any effort to describe them. Even if the pen of a skilled artist could succeed in portraying the passive vacant aspect of a chronic alcoholic, it must necessarily fail to depict the traitorous tremor which hovers about the corners of his mouth when he opens it to proclaim his temperance. The shifty eyes of the drug-taker, the

fatuous placidity of the patient with advanced insular sclerosis, the anxious look born of abdominal disease, the explosive suddenness with which the victim of double hemiplegia

bursts into laughter or tears, are only a few of the many familiar and striking lessons of the face which must be seen in real life if they are to be learned and utilized. On the other hand, there are facies the description and illustration of which may serve to impress their more important features on the minds of those to whom they are not familiar.

Cretinoid Facies. Compared with the general stunted growth of the rest of the body the head is relatively large. The face is broad, and remarkable for thick eyelids, broad flat nose, thick lips, and large coarse ears. The mouth is usually open and expressionless, the tongue may be more or less constantly protruded, and the chin is poorly developed (see DWYER, p. 232). The hair is scanty and brittle, the skin coarse, dry, and often almost yellow. Confirmation of the diagnosis may be sought in the dwarfed size of the child, the pendulous 'frog-belly' (Fig. 238), and the thick pads of subcutaneous tissue especially frequent above the clavicles. The lack of mental development, the slow pulse, and subnormal temperature complete the clinical picture.

Myxedematous Facies. The dulled intelligence of the patient is betrayed by the apathetic physiognomy

Fig. 238. —A female cretin, to show the 'frog-belly'.

(see Fig. 68, p. 50). Fig. 69 shows the same patient previous to the attack. The skin of the myxedematous face is coarse, dry, and sallow, occasionally with a flushed area over each cheek (see Fig. 391, p. 506). The puffiness of the eyelids may suggest nephritis (Fig. 392, p. 507), but the subcutaneous tissue is everywhere of firm consistence, and podgy rather than edematous. The nose is broadened, the ears thickened, and the lips so much swollen that more than the usual amount of mucous membrane is exposed. The hair is scanty, receding from the forehead, and the eyebrows are poorly marked. Similar conditions of hair and skin, together with brittle, striated nails, are found elsewhere. Masses of fatty tissue, like those described in cretins, may be found scattered about the neck and trunk. The slow speech, the expressionless face, and the general attitude of the patient may suggest paralysis agitans, but the diagnosis may be made by paying attention to the features just mentioned, by observing the slow pulse and subnormal

Fig. 239. —Dyspituitary obesity. There is none of the puffily eyelid appearance of myxedema. (Compare Fig. 68, p. 50).

temperature, and by watching the good effects of careful thyroid treatment. In dyspituitarism (Fig. 239), the eyelids and nose, in contrast to myxedema, are unaffected, and show no undue fatness.

Congenital Syphilitic Facies.

The victims of congenital syphilis, after ten or twelve years of age, may present a facies which is characteristic—an overhanging forehead, perhaps frontal bosses, a depressed nasal bridge (Fig. 240), striated scars radiating from the corners and other parts of the lips (Fig. 241), with a sallow, earthy complexion.

Fig. 240. —Congenital syphilis, showing prominent forehead and depressed nasal bridge. (By Dr. Rendle Short.)

Fig. 241. —Facies of congenital syphilis, showing notched teeth and sore angles of the mouth. (By Dr. S. A. K. Wilson.)

Closer observation of the eyes and teeth may detect the opacities of old keratitis and the

changes in the upper incisors which are claimed by Hutchinson to be pathognomonic (*Fig. 242*). These teeth are wide-gapped, irregular, and so deficient in enamel over the anterior and median parts of their cutting edges that the resulting crescentic notch gives them a striking appearance. Such a facies may accompany deafness, mental deficiency, physical infantilism, tibial deformities, and chronic arthritis, especially of the knee-joints. The diagnosis may be clinched if the blood gives a positive Wassermann reaction.

Myopathic Facies. Many cases of myopathy show no characteristic facies; others are remarkable for the loose pout of their lips at rest (*Fig. 243*) and the 'transverse' character of their smile (*rire en travers*) (*Fig. 244*). Both features are due to deficient facial musculature, and particularly to weakness of the orbicularis oris. The paresis of the orbiculares palpebrarum is only striking when an attempt is made to close the eye, although it may sometimes lead to prominent and perhaps staring eyeballs. In other instances there is a droop of the upper eyelids rather than any tendency to exophthalmos. The

chin tends to drop exhausted on her chest. The second depends on the characteristic myasthenic smile, sometimes more appropriately named a sneer (*Fig. 246*). This unfortunate and misleading facial expression is the result of deficient action on the part of the zygomatic and risorius muscles, and exemplifies the curious way in which some muscles are affected and others escape, in this disease, even when they derive their innervation from the same source. The accompanying photograph shows how a slight asymmetry in the muscular affections may be responsible for very different expressions on the two sides of the face.

The Facies of Exophthalmic Goitre. The facial appearance

in Graves' disease depends chiefly upon the 'stare' (*Fig. 247*). Surprise or fear is suggested by the prominence of the eyeballs and the retraction of the eyelids. The degree

inability on the part of the patient to whistle or to blow out his cheek quickly demonstrates the weakness of the orbicularis oris if it is not rendered obvious by the large amount of labial mucous membrane exposed while the mouth is at rest.

Myasthenic Facies. In patients suffering from myasthenia gravis there are two types of facies which can hardly be reproduced by other diseases. The first illustrates the exhaustion of the patient (*Fig. 245*): she can hardly keep her eyes open, and her

Fig. 245. Myasthenic facies: the appearance of fatigue produced by the drooping of the eyelids and drooping of the jaw is very apparent.

Fig. 246. Myasthenic facies: to illustrate a 'nasal' smile on the left side of the face, and a natural smile on the right.

of exophthalmos varies greatly, and it is not present in all cases: sometimes it occurs on one side and not on the other. Close observation shows that the sclera is visible between the edge of the iris and the eyelids, and that the usual harmony of movement between the eyeball and the eyelid is lacking. Normal winking is frequently much diminished or entirely in abeyance. The surface of the conjunctiva may be abnormally bright and glistening, and the secretion of tears may be excessive. In contrast with the white of the eyeballs there is often considerable dark pigmentation of the eyelids, which may also be the site of some oedema. The size of the pupils varies, undue dilatation occurring only in exceptional cases. A moist skin and a readiness to flush may often be remarked in the face.

Fig. 247.—Exophthalmic goitre.
(By Dr. S. A. K. Wilson.)

desires to look, before the head has assumed a corresponding position. Frequently the face has a staring expression, the eyelids being constantly retracted by the tonic spasm of the orbiculares palpebrarum. An absence of normal winking has been noted and ascribed to the same cause. In contrast with the slow development of facial expression under the influence of emotion, there is sometimes marked want of control over the fully developed emotional movement, and the patient complains that the exuberance of his laughter or tears is entirely out of proportion to his feelings of merriment or sorrow.

The facies of paralysis agitans is often simulated exactly by patients who are suffering or have suffered from an attack of encephalitis lethargica. This Parkinsonian syndrome, which includes the facies, stance, and gait of paralysis agitans, may develop rapidly during the acute stage of the encephalitis, and persist, perhaps in a modified form, for the

Fig. 248.—Facies of paralysis agitans: expressionless except as to the eyes.

remainder of the patient's life. In other instances it makes its appearance weeks, months, or years after the acute phase of the disease has subsided, and may progress slowly, so that the patient becomes gradually more and more disabled. In all cases, therefore, in which the syndrome is present it is important to elicit from the patient an exact history of the onset of his symptoms, and especially to inquire whether they coincided with or followed some transient illness which may have been wrongly and lightly diagnosed as 'influenza'. The post-encephalitic Parkinsonian syndrome may often be distinguished from that of paralysis agitans by the presence of disturbances in pupillary and other reflexes.

Fig. 249.—Tabetic facies. The photograph shows the partial bilateral ptosis and the wrinkling of the forehead, which contribute to the expression of sadness. (By Dr. S. A. K. Wilson.)

gives a sad expression. This drooping of the eyelid, which may be termed pseudo-ptosis or hypotonic ptosis, is not due to any paresis of the levator palpebrae superioris, as may be shown by the raising of the lid when the patient is looking up. It really depends on

Tabetic Facies. In a considerable percentage of cases of locomotor ataxy the appearance of the face is sufficiently striking, to a close observer, to afford a clue to diagnosis. The small size or the inequality of the pupils may first attract attention. The slight drooping of the upper eyelids, combined with some wrinkling of the forehead (Fig. 249), due to a compensating effort on the part of the frontalis muscle,

the fact that this muscle, like most of the muscles of the body, is in a condition of hypotonia. This allows the action of gravity to assert its influence, with the result that the lid hangs like a half-raised curtain in front of the eyeball. In other respects the face may be normal, but the majority of tabetics have a sallow complexion and very little subcutaneous fat, two facts which contribute to their generally unhealthy aspect. The writer believes that many victims of this disease exhibit a deficiency of the emotional reflex movements of the facial muscles. During conversation the play of the features in response to the subject of their talk is not so noticeable as that of healthy individuals.

Facies of Acromegaly. In the course of acromegaly changes in appearance frequently take place to such a degree that the patient becomes unrecognizable by friends who have known him only before the onset of his disease. These are the result of abnormal growth on the part of the bony and subcutaneous tissues in many parts of the body, and especially in the skull and extremities. The characteristic facies is brought about by osseous hyperplasia of the frontal ridges, the mastoid, zygomatic, malar, and nasal processes, while the lower jaw is usually enlarged in all directions. The prominent, arched brows, with retreating and wrinkled forehead, the massive nose, the long, thick upper lip, and the heavy chin (*Fig. 250*) form the most conspicuous features. The lower set of teeth may project some distance in front of the upper, and they are unduly wide apart. The tongue may be so enlarged as to keep the mouth open and to display many fissures and indentations as the result of its pressure against the teeth. The increased weight of the lower part of the face tends to make the head lean forward and perhaps ultimately to rest upon the sternum. In some cases the lower jaw is not affected, and the face may be described as abnormally square (*type carrée*).

Facies of Mongolian Idiocy. This facies is so characteristic that the diagnosis may often be made at sight (*Fig. 251*). The head is brachycephalic; the palpebral fissures

Fig. 250. A case of acromegaly, exemplifying the heavy enlargement of the front of the lower jaw.

Fig. 251. Achondroplasia with Mongolian rhinny. (By Dr. S. A. K. Wilson.)

Fig. 252. A Mongolian idiot in infancy. The photograph shows the oblique palpebral fissures and the large protruding tongue.

Fig. 253. A Mongolian idiot, showing a large flabby tongue, which is deeply fissured. (By Dr. S. A. K. Wilson.)

slant obliquely inwards and downwards towards a broad flat nose, rendered even broader by the presence of epicanthus; the eyelids show signs of chronic blepharitis; the ears are large and pitcher-shaped; the lips are fissured and often left open to allow a coarse tongue to protrude (*Figs. 252, 253*); the forehead is downy, and the hair of the scalp scanty, wiry,

and frequently mouse-coloured: the complexion is florid and mottled. The almond-shaped eyes, the presence of epicanthus, the florid complexion, and the absence of fatty masses serve to distinguish the Mongolian from the cretinoid idiot (*Figs. 254, 255*); in case of doubt the benefit or otherwise of thyroid treatment may clinch the diagnosis.

Fig. 254.—Male cretin, showing characteristic facies. Note the thick nose, thick lips, gaping mouth, heavy half-closed eyes, squat neck, and fat chin.

Fig. 255. The face and head of the same cretin seen in profile. Note the sparseness and coarseness of the hair.

Facies of Familial Lenticular Degeneration. The characteristic facies of this disease is only seen in advanced cases, and may be described as one of fixed emotion. The slightest attempt to engage in conversation may evoke an expression of exaggerated mirth (*Fig. 256*), which takes a long time to wear off and is quite unlike that seen in other diseases of the nervous system, although perhaps related to the spastic smile of double hemiplegia. The accompanying photograph also illustrates the tendency to fall to one side or the other when in the sitting position.

Fig. 256.—Facies of familial lenticular degeneration.

Facies of Mitral Stenosis. It is often possible to diagnose mitral stenosis at sight, on account of the remarkable malar flush and dark-red lips contrasting with the yellowish pallor of the forehead, peri-oral and perinasal skin (*Fig. 78, p. 69*). If one covers the malar regions and the lips the face looks sallow, but the malar flush and the dark-red lips give a look almost of plethora. Some normal individuals have a similar distribution of facial colour, but in mitral stenosis cases the facies is characteristic.

Facies of Splenomegalic Polycythæmia (Erythramia). The coloration is the chief feature of the facies in this malady, presenting a characteristic appearance which may be described as a combination of weather-beatenness, plethora, and cyanosis (*Fig. 515, p. 652*). The diagnosis

depends on discovering pronounced polycythæmia, generally with a moderately enlarged firm spleen.

Facies of Cirrhosis of the Liver. There is nothing characteristic of the facies when cirrhosis of the liver is in an early stage; nor can one diagnose the existence of cirrhosis with certainty even when the facies is that of chronic alcoholism, with its telangiectases over the cheeks, coarsening of the tissues generally, but especially on and round the nose and mouth, with purplish reddening in general—a familiar picture; but in the later stages of cirrhosis the sallow, dull, diffusely pigmented facies is often very characteristic, though the actual peculiarities may be defined with difficulty in words.

Facies of Pernicious Anæmia. The facies in pernicious anæmia may be absolutely characteristic in the later stages. There is no emaciation, but the colour is remarkable. Often described as lemon-yellow, it is more often a pale primrose-yellow, with a peculiar delicacy in the yellowish tint that is unmistakable when it is fully developed.

Facies of Acute Nephritis. The generally swollen look, the partial closing-up of the eyes by œdema, and the half-bloated look of acute nephritis with generalized œdema are characteristic; simulated only by the effects of insect bites or of angioneurotic œdema.

Facies of Polymyositis or of Polydermatomyositis. In this rare malady the symptoms affect many other parts besides the face: it is apparently a subacute streptococcal disease in which it is more or less accidental whether the skin, the muscles, the mucous membranes, the nerves, the subcutaneous tissues, the bones, or the serous membranes are most affected. There are many types, therefore polymyositis, polydermatomyositis, polydermato-neuromyositis, polydermato-mucoso-myositis, polydermato-neuro-mucoso-myositis, polydermato-osseo-neuro-mucoso-myositis, polydermato-neuro-osseo-mucoso-sero-myositis; all have prolonged pyrexia, and may be fatal; in a characteristic case the symptoms may simulate trichinosis, and the patient's face may present for continuous weeks an appearance which may be described as a combination of chronic erysipelas plus acute nephritis (*Fig. 559*, p. 702).

Facies of Acanthosis Nigricans.

The chief characteristic of this disease is the extreme pigmentation which develops in various parts of the body, but particularly on the neck or face, or both; the degree may be described as, more or less, what would result if a collier's hands were stroked over the parts affected, producing massive darkening, almost blackening, in the areas affected (*Fig. 257*). The most remarkable feature of the affection is that it nearly always indicates abdominal carcinoma, especially carcinoma of the stomach; and yet the patient may present himself for treatment on account of the pigmentation only, without any suggestion at the time that there is a carcinoma anywhere. It is probably an extreme degree, in special cases, of the liability to diffuse pigmentation of the skin that malignant disease in general tends to produce.

Facies of Addison's Disease.

Generalized darkening of the skin of the face may be the first thing to attract attention in a case of Addison's disease, but the distinctive character of the pigmentation is that it occurs in the mucous membranes within the mouth (*Figs. 500-502*, p. 644) as well as on the face.

Facies of Argylria. This condition is rare nowadays, though it was not uncommon when tabes dorsalis was treated with silver nitrate given orally. It may still be met with amongst workers in silver, and once seen it cannot be mistaken. The coloration is even and uniform, not patchy as in Addison's disease or acanthosis nigricans; it gives a semi-negro appearance, and it is a subcutaneous rather than a dermal pigmentation. It is rare but unmistakable.

Facies of Cyanosis. See CYANOSIS, p. 195.

F. Farquhar Buzzard.

FÆCES, MUCUS IN.—(See MUCUS IN THE STOOLS, p. 495.)

FÆCES PASSED PER URETHRAM. Faeces or faecal fluid are only passed per urethram when the bladder is in fistulous communication with some part of the bowel, or with some faeculent abscess cavity infected with the *Bacillus coli communis*. PNEUMATURIA (p. 646) is liable to occur at the same time. The chief causes are as follows :

- Cancer of the bladder opening into the rectum or into some loop of bowel which has become adherent to the bladder.
- Cancer of the rectum
- Cancer of the sigmoid colon
- Cancer of the caecum
- Cancer of the uterus opening both into the bladder and into the rectum
- Proctitis and periproctitis leading to the formation of an abscess which opens into the bladder
- Prostatitis and prostatic abscess opening into the rectum
- Rectovesical fistula from injury and sloughing, particularly after childbirth
- Caseous tuberculous disease opening both into the bladder and the rectum
- Appendicular abscess opening into the bladder
- An abscess resulting from acute diverticulitis (Telling's disease) opening into the bladder
- Pelvic actinomycosis.

The passage of faeces in the urine may be simulated by some cases of very fetid cystitis when the bladder has been infected by the *Bacillus coli communis*.

If the symptom is due to cancer, it matters little which viscus is the primary site by the time the growth has involved both bladder and bowel. The diagnosis resolves itself, therefore, into one between malignant conditions on the one hand and non-malignant on the other. If malignant disease is not obvious, it will nearly always be advisable to resort to surgical measures in the hope of curing the primary condition—rectal, appendicular, prostatic, or otherwise. The commonest causes other than malignant are local sloughing of the parts after labour, and faeculent appendicular abscess opening into the bladder. The diagnosis will be suggested by the history and confirmed by local examination or exploration.

FAINTING. The term 'fainting' permits of no concise definition, though what it implies is fairly clear : it includes mild and transient conditions such as 'coming over faint' without actual loss of consciousness, or an 'attack of faintness' ; but usually it implies that there has been partial or complete loss of consciousness as well, the patient having 'fainted right off' ; yet when the faint has been thus complete it is difficult to say sometimes where one would cease to use the term 'fainting' and substitute *Coma* (p. 153) instead. When faintings recur without obvious cause the general fear in the lay mind is that there must be serious heart disease, and it is to inquire about this that the patient often consults the doctor. Seldom, however, are faintings caused by actual heart disease ; far more often they are due to vasomotor or neurocardiac conditions, toxic, reflex, or the result of primary instability ; if a relatively young person faints several times in a year, it is practically certain that the heart itself is sound though the vasomotor nervous system is unstable ; apart from cases of heart-block, organic heart fainting occurs once only—the fatal syncope.

Fainting attacks may result from many different conditions, of which the following are some :

Emotion :

Sudden fright	Loathsome smell	First attendance at an operation
Noise	Unkind words	First attendance in the post-mortem room.
Unexpected joy	The sight of death	
Sudden grief	Sudden shock	
Horrible spectacle		

Exhaustion :—

Physical over-fatigue	Chronic illness, such as	Long hours of work
Starvation	phthisis or cancer	Lack of sleep.
Convalescence from illness	Prolonged standing	

Heat : Overheated rooms.

Cold.

Bad Ventilation : Church, theatre, concert-room, lecture-room.

Injury :

Severe general injury,
as in train or motor
smash

Blow over the solar plexus
Blow over the internal semi-
lunar cartilage of the knee

Contused testicle
Head contusions
Severe cuts.

Severe Blood Loss : -

1. With external bleeding :

Hæmatemesis
Hæmoptysis
Bowel hæmorrhage
Hæmaturia

Menorrhagia
Metrorrhagia
Placenta prævia
Post-partum hæmorrhage

From cut artery
From ruptured varicose
vein
Epistaxis.

2. With internal bleeding only :

Duodenal ulcer
Ruptured ectopic gesta-
tion

Internal bleeding after
operation
Leaking thoracic aneurysm

Leaking abdominal aneu-
rysm
Ruptured liver or spleen.

Pain : Whatever the cause, but particularly perhaps the pain of : -

Biliary colic
Renal colic
Labour

Frantic earache
Frantic toothache
Angina pectoris

Crises of tabes dorsalis
After injuries and fractures
Tic douloureux

Sudden Visceral Lesions other than those associated with bleeding :

Perforated gastric ulcer
Perforated duodenal
ulcer
Ruptured ectopic ges-
tation
Strangulated hernia

Acute intestinal obstruction
by a band
Pulmonary embolism
Acute pneumothorax
Inferior vena cava throm-
bosis

Mesenteric thrombosis
Mesenteric artery embolism
Dissecting aneurysm
Acute hæmorrhagic pancrea-
titis
Ruptured aortic valve.

Ascents to Heights : Mountaineering : Aeroplaning.

Descents to Depths : Coal-pits : Mines : Caisson work : Deep-sea diving.

Anæmia Not Due to Direct Blood Loss :

Chlorosis
Pernicious anæmia
Spleno-medullary leuka-
emia
Lymphatic leukaemia

Splenic anæmia
Lymphadenoma
Aplastic anæmia
Malaria
Tropical anæmia

Lardaceous disease
Ankylostomiasis
Bilharziosis
Worms.

Various Conditions : -

Addison's disease
Pregnancy : especially
at the quickening
Hysteria
Ménière's disease
Labyrinthine sclerosis

Cerebral tumour
Cerebral abscess
General paralysis of the
insane
Cerebral hæmorrhage

Cerebral embolism
Cerebral thrombosis
Epilepsy : fruste, petit mal,
grand mal
Heart-block.

Gases : -

Coal-gas
Products of incomplete
combustion: gas-fires,
motor-car exhaust
gases, coke ovens
Sewer gas

Bad drains
Petrol fumes
Carbon monoxide
Marsh gas
Sulphuretted hydrogen
Phosphuretted hydrogen

Arseniuretted hydrogen
Seleniuretted hydrogen
Carbon bisulphide
Naphtha fumes
Benzine
Other trade fumes.

Drugs :

Amyl nitrite
Trinitrin
Sodium nitrite
Digitalis

Coal-tar products such as
acetanilide, phenazone,
phenacetin, pyramidon

Anæsthetic fumes, especi-
ally chloroform, ether,
nitrous oxide.

Other Causes : -

Flatulence
Indigestion
Constipation

Collars or neck-gear that are
too tight

Simple faints without appar-
ent cause.

There is no need to discuss all the above in separate detail, for with most of them the diagnosis will either be obvious at once, or else the fainting will be associated with pain, bleeding, anaemia, or some other symptom which will be more helpful as a clue than is the fainting. The chief difficulty arises when the history does not at once give one some idea as to the nature of the attack, or when there is not much in the way of collateral symptoms to assist one, the fainting or faintings being the chief feature of the case. When the patient is young the main doubts that are likely to arise are expressed by the questions :—

Is my patient's heart really sound ?

Are these attacks really simple faints, or is my patient an incipient epileptic ?

When the patient is older, the queries may be :—

Are the attacks due to myocardial changes, heart-block, or arteriosclerosis ?

Has my patient had a slight stroke, called a fainting attack by way of euphemism ?

One can only answer the doubts sometimes by doing everything one can to exclude organic disease by thorough examination of all the systems, and then depending upon one's clinical judgement. If the faintings have been seen by oneself one can come to a conclusion more easily than if one has to rely upon the description of them by others. It is generally more easy to answer the query about the heart in a young subject than it is in an older person : fainting is very seldom due to organic heart lesion in the young ; it is a vasomotor phenomenon, due to misbehaviour of the sympathetic nervous system and not of the heart structure. Cases of valvular heart disease may faint, but the faints are no more dangerous in them than they are in organically sound persons. With older people this is not so true : faintings occurring for the first time in the latter half of life are less likely to be unimportant than they are in the young ; but even the old may faint from vasomotor causes that are not of great importance. One should investigate the state of the heart, however, with particular care, measuring the blood-pressure, determining the exact size of the heart by X-ray examination, and using the electrocardiograph : the latter is almost essential in detecting heart-block (*Figs.* 101, 102, 104, pp. 108, 109), a condition which may first indicate its presence by producing attacks of fainting without the full-fledged epileptiform phenomena of Stokes-Adams' syndrome.

The exclusion of *epilepsy* as the cause of apparently simple faints in the young adult may be extremely difficult : if the attacks are controlled by bromide treatment it does not follow that the condition is epileptic : there may, however, be some peculiar circumstance about one or more of the attacks—biting of the tongue, for example, or a peculiar groaning in the attack—to raise one's doubts to greater certainty ; or, after the faintings have recurred for years, a definite epileptic convulsion of grand-mal type may establish the diagnosis so that, looking back at the story, one sees that the recurrent faintings have been epileptic from the start. The great majority of faintings in the young, however, are otherwise than epileptic.

Distinction between a *slight stroke* and a simple faint is often impossible in an elderly patient ; if there is any asymmetry as regards reflexes, muscle power, or sensory phenomena, known not to have existed previously, the argument will favour stroke : if the blood-pressure is raised, the arteries thickened, the family history as regards strokes bad, the same applies ; but if there is no positive guide the tendency will be to diagnose a fainting, though perhaps with a shrewd suspicion that this faint was really a slight stroke.

Both *cerebral tumour* and *cerebral abscess* may be latent over long periods, and occasionally the only evidence they give takes the form of transient lapses of consciousness that simulate simple faintings : the ophthalmoscope should be used ; if there is optic neuritis, the diagnosis of something more than simple faintings becomes inevitable ; if no optic neuritis is yet present, the true nature of the case may become clear only with the developments that time brings.

Duodenal ulcer cases merit special mention, for it is not uncommon for the first symptom to be an attack of unaccountable fainting, generally when the patient is at work ; there may be no abdominal pain whatever, but the ulcer has bled internally and the fainting is due to the acute blood loss. The pallor may be attributed at the time to the effects of the fainting ; but when it persists, and particularly when there is melæna the next day or the day after, the true nature of the case becomes clear ; the diagnosis may be

missed, however, if the stools are not examined, for there may be no hamatemesis. One meets with cases in which there have been two or even three such faintings in a fortnight before the duodenal ulcer character of the case has been realized.

Addison's disease is diagnosed by the pigmentation of the skin and buccal mucosa associated with the low blood-pressure: but recurrent faintings of alarming severity may occur at any stage of the disease, and they may precede the development of the characteristic pigmentation.

Even when, by a process of exclusion, it seems clear that a patient's faintings are of 'simple' type, search should be made for possible causes, either toxic within the patient or in the form of drugs or gases from without. Women naturally faint more readily than men, and those with intrinsic instability of the nervous system more readily than those of robust nervous type: if faintings begin in one who has hitherto seemed other than of a fainting type, some toxin may be at work: early phthisis, for example, or chronic poisoning from septic tonsils, and such things should be sought out and cured. Again, there may be chronic poisoning as the result of a gas escape in the bedroom, a badly ventilated gas-fire: or the patient may spend much time in his garage with the engine running so that exhaust gases are getting into his system: or his work may entail the use of chemicals which engender fumes that affect his health: or the patient may be unduly susceptible to some drug which has been taken, such as phenacetin for headaches: often it is impossible to discover anything of the kind, but sometimes a successful clue can be found and followed up, four of the commonest being slightly leaky gas-pipes, ill-ventilated gas-fires, petrol-exhaust fumes in garages, and gases from badly ventilated drains. *Herbert French.*

FAT IN THE URINE. (See CHYLURIA, p. 140.)

FATTY STOOLS. In order to determine the total fat and fatty acid in the faeces, these may be evaporated with 1 per cent hydrochloric acid in alcohol on the water-bath, and dried in the water-oven until of constant weight. A weighed quantity of the dried material is then extracted with ether in a Soxhlet apparatus for twenty-four hours: the resulting ether extract, after filtering, is placed in a weighed vessel and evaporated on the water-bath, and finally dried in the water-oven until of constant weight. This product includes a certain amount of pigment, water-soluble acids, cholic acid, cholesterol, and coprosterol. These may be determined by suitable methods, but, as their weight is small, they are usually neglected.

If the process is repeated without the addition of hydrochloric acid in the first stage, the result measures the neutral fat plus free fatty acids without the fatty acids present as soaps, so that the difference between the percentages of dried material obtained in the two extractions measures the fatty acids present in the faeces as soaps.

Finally, if the second extract is redissolved in ether and alcohol and titrated with $\frac{N}{10}$ alcoholic caustic potash, using phenol phthalein as indicator, until a pink colour is obtained, the titration gives a measure of the free fatty acids present, which can be expressed in terms of stearic acid on the basis that 1 c.c. $\frac{N}{10}$ potash represents 0.0284 grm. of stearic acid. Subtracting the figure for free fatty acid from that for neutral fat plus free fatty acid, the remainder represents neutral fat plus small quantities of other substances, of which liquid paraffin would be the most considerable if it were present.

A more correct figure for neutral fat would be obtained by adding a known excess of N alcoholic potash after the titration for fatty acid, heating on the water-bath with a reflux condenser for fifteen minutes, cooling, and titrating back with acid, to determine the amount of potash remaining. The potash used would represent the fat hydrolysed on the basis of 1 c.c. N potash = 0.284 grm. of stearic acid. In practice, however, when there is no paraffin present, the figure for neutral fat is determined with sufficient accuracy for clinical purposes by the method of difference indicated above.

A more rapid and less elaborate procedure for determining these quantities has been devised by Cammidge, which is similar in principle, and gives results sufficiently accurate for clinical purposes. This is as follows: The faeces are first dried to a constant weight with or without the addition of alcohol, but without addition of acid. They are then

ground as finely as possible in a mortar, and two portions of about 0.5 gm., each are weighed accurately and each washed into a Schmidt-Werner milk tube, the first (A) with 10 c.c. water, the second (B) with 3 c.c. strong hydrochloric acid diluted to 10 c.c. with water. The two tubes are then heated on the water-bath for fifteen minutes, being occasionally shaken slightly, or rotated between the palms of the hands, to encourage mixing. After cooling, water is added up to the 20 c.c. mark and ether up to the 50 c.c. mark : by inverting the tubes many times sufficiently complete extraction is obtained. The tubes are then placed in a vertical position until the ether has separated and cleared by sedimentation, which process may be assisted by occasionally rotating the tubes between the hands. Two small flasks are now dried and weighed : 20 c.c. of each ether extract is measured out with a pipette, each into a flask, the ether is evaporated, and the flasks are dried in the water-oven to a constant weight. The ether remaining in the tubes is measured by means of the graduations in the middle part of the tube, and a correction made thus : Suppose 20 c.c. extract A gave 0.1 gm. residue and the ether remaining in the tube was 7 c.c., then the extract obtained from the weighed amount of faeces, say 0.5 gm., was $\frac{0.1 \times 27}{20} = 0.135$ gm., or 27 per cent.

A gives neutral fat plus free fatty acid.

B gives neutral fat plus free fatty acid, plus fatty acids present as soaps, which have been liberated by heating with the hydrochloric acid.

As before, the free fatty acid in A may be titrated with alcoholic potash and the neutral fat obtained by difference.

Some of the fatty material in the faeces comes from intestinal secretions : as regards fat in the food, up to a certain point the greater the amount ingested the higher is the proportion that is absorbed, until an optimum is reached : above this optimum point the proportional absorption of fat is less efficient. Fats with a high melting-point are less well absorbed than are those with a lower melting-point : and fats which are protected by a coating of cellulose or fibrous tissue may to a certain extent escape digestion : so before one can draw conclusions as to the significance of fat residues in the stools, one needs to know not only the total amount of fat taken in the diet, but also the precise nature of the fat taken. Normal adults on an adequate milk diet, say six pints daily, absorb on the average 94 per cent of the fat in the milk. In infants the fat lost, when the diet is cow's milk, is from 10 to 25 per cent of that in the food.

However, a good deal of information may be obtained by studying the proportions of residual fat in a sample of dry faeces, when an ordinary mixed diet is given. The normal figures for the adult are :

Total fat and fatty acid	15 to 25	per cent
Neutral fat	1 to 2	unsoaped fatty acids,
Free fatty acids	9 to 13	10 to 15 per cent
Fatty acids as soaps	10 to 15	per cent

The fatty acids as soaps and the free fatty acids plus neutral fat are in the normal about equal, and the free fatty acids are about nine times as much as the neutral fats.

Failure to absorb a due proportion of the fatty acids obtained from the food may be due to :

Deficiency of Bile. The fat is split, but imperfectly absorbed. The total figure is above normal, the increase in the faeces being mainly in the form of soaps. The relative proportion of neutral fat is not increased. The faeces are typically neutral or alkaline in reaction, and contain an obvious excess of soap crystals and no fat globules when examined under the microscope.

Deficiency of Pancreatic Juice. This may be due to carcinoma of the pancreas, to chronic pancreatitis, or to obstruction at the ampulla of Vater. There is a failure to split the fat of the food. The figure for total fat is above the normal, and the relative proportion of neutral fat is raised to an extent dependent on the degree of pancreatic deficiency. There is frequently biliary deficiency as well, but this does not prevent the proportion of neutral fat from being high.

Typically the faeces are acid, and contain fatty acid crystals and globules of fat. Undigested meat fibres may be seen. The acid reaction is partly due to imperfect

digestion of carbohydrate as well. Further information can be obtained by determining the diastase in urine or blood.

Lymphatic Obstruction. This interferes with the absorption of fat after it has been split. The total figure is increased, the increase being mainly in soaps, and the proportion of neutral fat is not increased. The faeces are not acid in reaction. Usually, but not always, they contain an obvious excess of soap crystals. One might find, for example, that soap crystals are not conspicuous, but that the faeces are bulky, that the fatty acids as soaps are 31.5 per cent, the free fatty acid plus neutral fat 18.1 per cent of the dry faeces.

Sprue. This gives results analogous to those of lymphatic obstruction.

Gastro-colic and Jejuno-colic Fistula. Both the total fat and the proportion of neutral fat are increased; the faeces are usually acid, and show both fat globules and fatty crystals microscopically.

Congenital Steatorrhœa. The faeces contain an obvious excess of fat, which separates as oily droplets. The proportion of neutral fat is not remarkably high. *J. H. Ryffel.*

FAVUS.—(See FUNGUS AFFECTIONS OF THE SKIN, p. 309.)

FEMORAL SWELLING. (See SWELLING, FEMORAL, p. 824.)

FEVER. (See HYPERPYREXIA, p. 390; and PYREXIA, p. 687.)

FINGER, SORE. Digital lesions may be erythematous, papular, vesicular, bullous, pustular, squamous, or ulcerative, representing a long list of cutaneous affections. The *erythematous* affections which may attack the fingers are erythema, lupus erythematosus, eczema, urticaria, chilblains, and frostbite; the *papular*, lichen planus and granuloma annulare, pityriasis rubra pilaris, angiokeratoma, eczema, and papular syphilides; the *vesicular*, scabies, cheiropompholyx (dysidrosis), eczema, dermatitis herpetiformis, chilblains—the irritation set up by the habitual handling of sugar, or (in washerwomen) by immersion in water containing soda, or by contact with such vegetable irritants as rhus, mustard, thapsia, the common orange, eucalyptus leaves, arnica, etc.; the *bullous*, pemphigus, epidermolysis bullosa, dermatitis herpetiformis, scabies, leprosy, and syphilis (chiefly in infants); the *pustular*, scabies, boils, whitlow, impetigo contagiosa, eczema, and pustular syphilide; the *squamous*, psoriasis, eczema, ichthyosis, lichen planus, syphilis, acanthosis nigricans, and verruca necrogenica; the *ulcerative*, bed-sore, chilblains and frostbite, X-ray ulcer, dissection wounds, lupus vulgaris, lupus erythematosus, leprosy, chancre and syphilitic ulcer, epithelioma, Raynaud's disease, diabetic gangrene, trophic ulcer, and scleroderma.

The diagnosis of these various affections will be found under the names of the primary lesions papules, vesicles, etc. and here it is only necessary to particularize bed-sore, diabetic gangrene, verruca necrogenica, dissection wounds, and chancre. *Bed-sore* on the fingers is caused by friction between the knuckles and the bedclothes as the patient raises himself to the sitting position. It begins as erythema, and its significance can hardly be mistaken, though its presence in such a situation may take the nurse by surprise. *Diabetic gangrene* most frequently attacks the toes or other part of the foot; but occasionally it has been observed in the penis, and in some cases the fingers have been affected. *Post-mortem wart*, or post-mortem pustule, the condition sometimes met with chiefly on the knuckles and in the interdigital folds in those who have to handle dead bodies, whether of human beings by mortuary attendants or of the lower animals by butchers and slaughterers, is a form of tuberculosis, caused by infection with living bacilli from the dead tissue. It is sometimes met with also in colliers, in whom the site of inoculation is probably an abrasion received in the handling of coal. The pustule, beginning as a flat papule, dries up and forms a scab, which, when it falls off, leaves a surface that is made irregular by overgrowth of papillæ. These grow and become harder, until they form a warty mass. The avocation of the patient will suggest the true nature of the lesion. Of *dissection wounds*, consisting of pustules or small abscesses on the site of a puncture or scratch, or of lymphangitis and cellulitis, which may be followed by pyæmia, the history will supply the diagnosis. In *chancre* of the finger, usually met with in midwives, nurses, and medical men, but occasionally in others, a favourite situation of the sore is

at the lateral nail-groove, and in many cases the lesion first attracts notice as a persistent fissure. If the sore undergoes induration, and there is general enlargement of glands with the other well-known secondary symptoms, the diagnosis can no longer be doubtful.

Dairymaids, milkers, and other farm hands sometimes develop acute or chronic sores upon their fingers due to *cow-pox* caught from the teats or udders of infected cows, and such patients may inoculate others who have no work that is connected directly with cows. The appearances are those of persistent boils or whitlows, and the diagnosis may be very difficult unless the source can be traced. Two other varieties of whitlow may pass entirely without recognition unless bacteriological methods are resorted to, namely, onychia or perionychia due to Klebs-Loeffler bacilli (digital diphtheria), and similar trouble due to the *Bacillus coli communis*.

Sore fingers due to *Raynaud's disease* or to *frostbite* can be diagnosed from collateral evidence in individual cases: the deformities produced by scarring after local necrosis or superficial gangrene resulting from Raynaud's disease may sometimes be extreme. *Syringomyelia* may sometimes take the form of recurrent sores on the fingers, or apparent whitlows followed by scarring and deformity (Morvan's disease) owing to the patient's inability to feel pain or extreme heat as distinct from simple touch: the diagnosis of the lesion of the spinal cord may be suggested by the condition of the fingers. In rare cases a spontaneous soreness of a finger tip may be the first indication of *infective endocarditis*, the heart lesion being unsuspected until its existence is suggested by a peripheral embolus, for instance in a finger. Ernest Dore.

FITS.—(See CONVULSIONS, p. 180.)

FLATULENCE. It is important to distinguish between: (1) *Gastric flatulence*, in which wind is eructated; and (2) *Intestinal flatulence*, in which it is passed per anum.

Gastric Flatulence.—Before concluding that excess of gas is being produced in the stomach it is necessary to exclude the possibility of *air-swallowing* (*aerophagia*, *eructatio nervosa*). This is common, but is apt to be interpreted wrongly. It is met with often in women about the menopause; it is also by no means infrequent in young men prone to be 'neurotic', or to exhibit signs of neurasthenia or psychasthenia, though otherwise healthy. *Eructatio nervosa* is recognized by the violence of the belching and the excessive amount of wind expelled. It comes on in attacks both by day and by night, sometimes annoying the patient. If a patient can belch 'to order', one may conclude with almost perfect certainty that he is suffering from this form of neurosis; and by watching him during the attack one can recognize that he is gulping down air.

Fig. 258.—Sarcinae ventriculi.
(Medium power.)

True gastric flatulence is present to a greater or less degree in many one might almost say in all forms of gastric disorder. For purposes of diagnosis one must distinguish between the cases in which gas is produced by *fermentation* in stagnating gastric contents, and those in which no such fermentation is taking place. In the former the stomach is dilated and vomiting is almost certainly present: if examination of the gastric contents shows delay in their transmission, and the presence of *sarcinae* (Fig. 258) and yeasts, one may diagnose pyloric obstruction, either simple or malignant. In these cases the eructations are sometimes offensive, revealing the existence of putrefaction in the gastric contents, and in rare cases they are inflammable from the presence of marsh gas. Occasionally one meets a case in which the breath catches fire if belching occurs whilst a pipe is being lit. X-ray examination will confirm the delayed emptying of the stomach.

Non-fermentative flatulence accompanies most forms of functional disorder of the stomach; but is specially prone to occur in gastric atony. In that case there will be a

well-marked splash over the gastric area, even some hours after a meal, but without any evidence of actual dilatation of the organ, although there may be some gastropnoia. (See also INDIGESTION, p. 395.) In other forms of gastric disorder flatulence is only a minor symptom, and of little diagnostic value.

Flatulence is also not an uncommon symptom in *emphysema of the lungs*, and in cases of *cardiac disease*, especially when due to degeneration of the heart muscle. In elderly persons these conditions should always be looked for. In *angina pectoris*, also, flatulence may be a prominent symptom, but in that case the attacks tend to come on after exertion, and are accompanied by the characteristic pain of angina.

Intestinal Flatulence may be either *acute* (see METEORISM, p. 485), or *chronic* (intestinal flatulence proper). In the latter case it is often attended by colicky pain which is relieved by the passage of wind. Flatulence is not a feature of ordinary constipation: when marked, it is suggestive of either chronic obstruction or intestinal fermentation.

If *obstruction* is present, coils of intestine undergoing peristaltic contraction are often to be seen, and there is pronounced constipation, sometimes alternating with diarrhoea. A diagnosis of the exact cause of the obstruction may necessitate the use of the sigmoidoscope, the X rays, or even an exploratory operation. In cases of *intestinal fermentation*, either constipation or diarrhoea may be present. Microscopic examination of the stools is often of help in elucidating the nature of the fermentative process, undigested muscle fibres (protein fermentation or putrefaction) or an excess of starch cells (carbohydrate fermentation) being seen. (See DIARRHOEA, p. 214.)

Robert Hutchison.

FLUSHING. The difference between flushing and blushing is that the former only occasionally, the latter invariably, arises from emotion—shyness, shame, and modesty. A flush may begin instantaneously in all the parts in which it is felt, or, arising in a lower region, it may ascend to the head, or, beginning in the head, it may descend to some part of the body, or it may pass both upwards and downwards. The sensation varies in severity, and may be actually painful. The nerve-storm generally ends in a cold stage, though this may precede the hot stage. The cutaneous symptoms may be accompanied or followed by nausea, vomiting, fainting, a sense of suffocation, numbness, tremors, tinnitus, giddiness, palpitation, paresis. The physical states and conditions from which flushing arises include menstruation and menstrual irregularities, the climacteric, pregnancy, lactation, chlorosis, indigestion often associated with hypochlorhydria, feeble circulation, general debility; it may also be an expression of emotion, may be caused by alcoholic indulgence, or may merge into an epileptic aura. It is commoner in women than in men, but may disturb the latter as a male climacteric phenomenon: and in certain cases of double castration for disease of the testicles it may be a distressing after-result—recurrent acute flushings of the face, with or without perspirations but always with a sense of great heat—afflicting the patient several times a day, preventing him from accepting engagements, and resisting treatment of all kinds for years. If it becomes chronic, the skin of the face, especially of the flush area—the middle third of the face—is reddened permanently, and the condition becomes one of *rosacea*: sooner or later the superficial vessels undergo dilatation: hypersecretion and retention of sebaceous matter follow, and inflammation may be set up: the inflammatory process, becoming chronic, may give rise, especially if the patient is much exposed to the weather, to hypertrophic thickening of the skin of the nose, with lobulation (rhinophyma).

The condition or habit which is the cause of *rosacea* will be deduced from the history, especially as regards tea, alcohol, and dyspepsia, and from examination of the patient: there is generally very diminished free hydrochloric acid in the gastric juice, or a test meal may show complete achlorhydria. *Rosacea* is distinguished from *acne vulgaris* by the absence of comedones, the redness of the affected surface, the limitation of the eruption to the face, especially the nose and cheek—butterfly area—the telangiectasis, the hypertrophy, and by its being an affection of middle life rather than of puberty. It differs from *lupus erythematosus* in the absence of scabiness and of atrophic scarring, in the border, which is not raised and shows no signs of active spreading, and by its fluctuations. *Seborrhoeic eczema* may be met with in the flush area, but it is usually associated with seborrhoea capitis, there is no telangiectasis, and the affected surface is oily or scaly. From

tertiary syphilides, rosacea is distinguished by its slow course, its symmetry, the dilatation of blood-vessels, and the absence of any tendency to ulceration and scarring, or to atrophy. In syphilis, further, there will be the stigmata or the history of earlier lesions.

FOUL BREATH.—(See BREATH, FOULNESS OF THE, p. 112.)

FRACTURE, SPONTANEOUS.—Spontaneous fracture signifies fracture of a bone from causes which ordinarily would have been inadequate. Tremendous muscular efforts sometimes lead to the breaking of bones without any external violence, but this variety would not be included under the heading of spontaneous fracture if the degree of muscular effort seemed adequate. A man has been known, for instance, to dive into shallow water, and in order to bring himself to the surface quickly, and prevent his head from striking the bottom, he has used his neck muscles so strenuously in bending his head back as actually to fracture his vertebræ. This fracture is not spontaneous, but due to excessive muscular exertion. There are three main groups of causes for true spontaneous fracture, namely, excessive brittleness, or innate lack of strength of the bones—*fragilitas ossium* ; general paralysis of the insane ; and unsuspected lesions of the bones, particularly myeloid sarcoma, chloroma, tuberculous caries, or secondary deposits of carcinoma or sarcoma.

Fragilitas Ossium.—When the first fracture occurs in such a patient, there may be doubt as to the diagnosis ; but when repeated breaking of different bones occurs, in each

Fig. 259.—Blue sclerotics which accompany brittle bones liable to spontaneous fracture (*fragilitas ossium*).
(From a case under the care of Dr. Forman.)

case from apparently trivial causes, the diagnosis becomes clear. The undue fragility may show itself in early life, but more often not until the patient has reached adult stature and weight. There is a very remarkable familial type of the disease, in which successive generations contain some members who have fragile bones amongst others who are

healthy; the latter have white sclerotics, whilst those exhibiting *fragilitas ossium* have sclerotics that are definitely blue (*Fig. 259*)—sometimes even dark blue. Both bones and sclerotics lack part of their proper matrix; the diagnosis is easy, though the condition, termed

'blue sclerotics with brittle bones', is rare.

Two maladies which differ from *fragilitas ossium*, and yet which may cause undue bending, or partial or green-stick fracture of bones, are *rickets* in children, in which disease, for a time at least, there is excess of preparation for bone formation, but deficiency in completing the ossifying process, so that the bones, being unduly soft, not only bend, but also give way as a green stick would, causing the partial or green-stick fracture; and *mollietas ossium* (*Figs. 260, 261*), a rather rare affection in this country, though reported to be less uncommon in certain parts of the Continent, notably in the Rhine valley, coming on especially after pregnancy, and associated with concentric thinning of the bones from the marrow outwards, so that they eventually consist of a mere shell, which bends with undue ease, and may sometimes break spontaneously. The relationship to pregnancy may suggest the diagnosis, and

Fig. 260.—Photograph of a case of *mollietas ossium* in a man of 35, showing the extreme twisting and deformity of the legs in particular. (*Fig. An. Anglon. Newcastle.*)

there is no other disease which produces the same degree of pathological softening, bending, and fragility of the bones in adults; active rickets is practically confined to young children, only a few cases having been recorded during adolescence, and none in adult life.

Spontaneous fractures in *general paralysis of the insane* occur, like the aural hematomata of this disease, at a late stage when the patient is bedridden. They may arouse suspicion that the attendants have been unduly rough in their handling of the patient; but so atrophic do the tissues, and particularly the bones, become, that the latter may fracture from slight and otherwise inadequate causes. The diagnosis will have been made months or more previously, by reason, first, of the mental changes of the patient, particularly ideas of grandeur; and secondly, by the occurrence of convulsive seizures after there have been changes in the patient's mental condition for a longer or shorter time. The case is generally that of a man who has suffered previously from syphilis, for which treatment was not very prolonged, and whose business has entailed much mental hard work, and possibly worry, in a city. Confirmatory evidence may be obtained,

if need be, by finding relatively large numbers of small lymphocytes in the cerebrospinal fluid removed by lumbar puncture, and Wassermann's serum reaction for syphilis may be positive in the blood or cerebrospinal fluid or both.

Fig. 261.—Skiagram from the same patient as *Fig. 260*, showing the deformity and thinness of the bones.

Before concluding that spontaneous fracture of a bone is due either to neurotrophic causes, or to fragilitas ossium, it is important to exclude the possibility of primary or secondary *new growth* in the affected bone, or *tuberculous caries*. It may be that the patient is already suffering from a bony swelling, such as myeloid sarcoma, before the fracture takes place, or it may be known that there is, or has been, a primary growth elsewhere; for instance, in the pelvis, breast, stomach, or thyroid gland, in which case the spontaneous fracture of a bone would suggest that a metastasis has occurred at the site of fracture, eroding the bone until it finally broke from a trivial cause. The chief difficulties arise, first, when there are no symptoms of the primary growth itself, for instance in the case of a diffuse carcinoma of the stomach of the indiarubber-bottle type; and secondly, when the patient is really suffering from tuberculous caries whose existence has been entirely unsuspected. As an instance, one might mention the case of a woman fifty years of age, who, seeming to be in perfectly robust health, was standing in her kitchen, when her son entered unexpectedly, causing her to start suddenly, giving her body a twist at the same time. This movement was followed immediately by paralysis of both legs, and it seemed as though the sudden muscular exertion had led either to a hemorrhage or to a fracture-dislocation of the spine: the cause for the fracture was in itself inadequate, however, and it would not have produced the symptoms had there not been spinal caries which had been slowly eroding the bones for some time previously, until they now gave way as the result of what would otherwise have been a trivial movement. The diagnosis in cases of the kind depends chiefly upon remembering the possibilities, and not omitting a careful examination of every part of the body. When the X rays are available, they may sometimes be of considerable value in detecting a neoplasm (*Figs.* 638-641, pp. 822, 823) or a tuberculous focus (*Fig.* 451, p. 565) in the affected bone. *Herbert French.*

FRAGILITAS OSSIUM. (See FRACTURE. SPONTANEOUS, p. 304.)

FREQUENCY OF MICTURITION.—(See MICTURITION. ABNORMALITIES OF, p. 490.)

FULLNESS, SENSE OF.—A sense of fullness is experienced when the tension exerted on the muscle fibres of the stomach or intestines is greater than normal.

Localization. A sense of fullness felt in the upper part of the abdomen, in the neighbourhood of the umbilicus, and in the lower part of the abdomen is generally due to distention of the stomach, small intestines, and colon respectively.

1. Gastric Fullness.—The bulk of gastric contents, whether fluid or gas, required to produce a sense of fullness depends upon whether the tone of the muscles of the stomach is (a) Normal, (b) Excessive, or (c) Deficient. The sensation is the same in each case; the patient commonly believes it is due to excess of gas in the stomach, and it is generally thought that tone is deficient; but the former is rarely true, and the latter is certainly not more commonly the case than the reverse.

a. In normal individuals the sensation of fullness is produced by eating very rapidly, as the intragastric pressure rises owing to the relaxation of tone, which should proceed *pari passu* with the increasing bulk of the gastric contents, taking place with insufficient rapidity.

b. When the tone of the stomach is increased, a comparatively small quantity of food produces a sensation of fullness unless the food is eaten with extreme slowness. The condition is common in patients who are nervy; it occurs in both sexes, but is much commoner in women than in men; the patient may sit down to a meal prepared to eat heartily, but before the meal is finished—sometimes, indeed, after only a few mouthfuls have been swallowed—there is such a sense of over-fullness of the stomach that the patient can eat no more; or, in another type of the same condition, the meal is eaten without discomfort, but shortly afterwards clothes have to be loosened or stays taken off to give relief to the sense of over-fullness which may be almost unbearable; the cause is nearly always a misbehaviour of the nervous mechanism of the stomach, and not the result of local gastric disease. In rare cases the stomach is abnormally small owing to infiltration of its walls with cancer (leather-bottle stomach, *Fig.* 281, p. 342): as its capacity cannot then increase at all by relaxation of its muscular coat, a very small quantity of food produces an immediate rise in intragastric pressure and a corresponding sensation of fullness.

c. In atonic dilatation of the stomach the muscle-fibres are relaxed completely before any food is eaten; the weight of the food, however slowly it is eaten, stretches the fully relaxed fibres from the minute it is eaten, and a sensation of fullness is felt.

In slighter cases (hypotonus) the muscle-fibres are not relaxed completely, but complete relaxation occurs as soon as a small quantity of food has been eaten; any further addition to the gastric contents produces a sense of fullness.

From these considerations it is clear that: (1) If a sense of fullness is only felt when an excessive quantity of food is eaten, the size of the stomach is probably normal, and the excess is the cause of the symptom; (2) If it is only felt when food is eaten very rapidly, the size of the stomach is probably normal, and the bolting is the cause of the symptom; (3) When it is felt in spite of the food being normal in quantity and eaten at the normal rate, it is due to hypertonus or hypotonus if it can be prevented by eating small meals very slowly, and to atony or to leather-bottle stomach if this is not the case.

The distinction can only be made with certainty, however, by estimating the tone of the stomach directly, or indirectly from its size, a hypertonic stomach being small, whereas a hypotonic or atonic stomach is large.

Although percussion gives some idea of the quantity of gas in the stomach it does not help in the determination of its size, and auscultatory percussion and friction have been shown by means of the X rays to be quite valueless so far as the stomach is concerned.

Splashing and succussion occur in the normal stomach after an ordinary meal; if, however, they can be produced after drinking two ounces of water on an empty stomach, atony is probably present.

Inflation is the only method apart from the X rays which gives definite information as to the size and tone of the stomach. The patient drinks on an empty stomach two quantities of water in rapid succession: $1\frac{1}{2}$ drachms of sodium bicarbonate are dissolved in one, and $1\frac{1}{2}$ drachms of tartaric acid in the other. At the body temperature and atmospheric pressure, 1700 c.c. of carbon dioxide are evolved. The normal stomach has a capacity of 600 to 1200 c.c. when filled rapidly: the 1700 c.c. of gas are therefore subjected to a considerable degree of tension; a certain amount of discomfort is felt, and the gas is expelled rapidly on sitting up. When the tone of the stomach is excessive, the capacity is less than 600 c.c., and when it is deficient it is more than 1700 c.c.: in the former case a sensation of painful fullness is produced, and the gas is expelled violently on sitting up; whereas in the latter case no discomfort, and sometimes actual relief, is experienced, and the gas can be expelled only with difficulty.

The tumour formed by an inflated hypertonic stomach is generally situated too high to be accessible for palpation, but when it can be reached it is found to be firm and well defined: with a normal stomach it is also firm and well defined, and is often visible through the abdominal wall; whereas with a hypertonic stomach it is soft, and its outline is less easy to determine by palpation and percussion. When the inflated stomach is outlined by means of palpation and percussion, the distance between the lesser and greater curvatures of the stomach should be between 3 and 4 in., and the greater curvature should reach within an inch of the umbilicus in the horizontal posture. The distance between the curvatures in a hypertonic stomach is less than 3 in., and the greater curvature is more than an inch above the umbilicus; in atonic dilatation the distance is more than 4 in., and the greater curvature often reaches below the umbilicus.

The size and tone of the stomach can be determined most accurately by examining the patient with the X rays in the vertical posture after a meal of porridge containing 4 oz. of barium sulphate. Owing to the adaptation of the tone of the normal stomach to the volume of its contents there is little difference in the upper level of the semi-fluid chyme as seen in the erect position, whether the volume is 5 oz. or 2 pints, and the greater curvature is not more than an inch above or an inch below the umbilicus. A hypertonic stomach is diagonal, or even horizontal, instead of almost perpendicular as in normal individuals, and its lowest extremity is situated at least an inch, and often considerably more, above the umbilicus. An atonic stomach does not adapt itself to the volume of its contents: food taken when it is empty drops at once to its most dependent part, instead of being held up for a few seconds by the tonic contraction of the body of the stomach. As more and more food is taken, the upper surface of the gastric contents gradually rises, but it never reaches the height observed in normal and hypertonic

stomachs after the first two or three mouthfuls of food are swallowed. The gastric tone is insufficient to withstand the weight of the food, and the greater curvature consequently sinks as the quantity of gastric contents increases.

Most patients ascribe a sense of fullness in the epigastrium to 'wind', and try to relieve their discomfort by eructation; as, however, it is rare for excess of gas to be present, the attempt leads to *aërophagy*. The sense of fullness is thus often aggravated by *aërophagy*, though primarily due to some other cause. In addition to ascertaining the tone and size of the stomach it is therefore necessary to discover whether the sense of fullness is in part due either to excess of gas produced by fermentation or to secondary *aërophagy*. The presence of excess of gas in the stomach can be ascertained most readily by means of the X rays, as it is often difficult to distinguish by percussion whether a collection of gas is in the stomach or in the splenic flexure.

Excess of gas is only produced in the stomach when evacuation is delayed: this never occurs in a hypertonic stomach, and only in a normal stomach when an excessive quantity of food has been eaten. In atonic dilatation of the stomach stasis is never sufficiently great for much fermentation to occur, the only condition in which it is really active being dilatation due to pyloric obstruction. This can readily be distinguished from atonic dilatation with the X rays, even before the onset of visible peristalsis and the characteristic vomiting of large quantities of food eaten many hours earlier, by the excessive activity of peristalsis, the occurrence of retro-peristalsis, and the presence of a large residue in the stomach six hours after a barium meal. The diagnosis of pyloric obstruction is confirmed if the passage of a stomach-tube at 9 a.m. shows that remnants of a dinner taken at 9 p.m. the previous evening are still in the stomach, nothing having been eaten or drunk in the interval.

Aërophagy can be diagnosed with certainty if eructation occurs six or more times in rapid succession, or if it occurs before breakfast, unless food is present in the stomach as a result of pyloric obstruction. The air-swallowing may take place without the least consciousness of the fact on the patient's part, but one can often detect the air-gulping clinically, and it is quite easy to watch the whole process of *aërophagy* with the X rays.

2. Intestinal Fullness.—A sense of fullness in the lower part of the abdomen is almost invariably due to the excessive tension on the intestinal walls produced by the presence of an excessive quantity of gas. The only symptom which proves conclusively that this is the case is the passage of excess of flatus, particularly if it is found to relieve the discomfort. In the absence of evidence of a hypertonic condition of the colon, such as occurs in spastic constipation, a sense of fullness in the lower part of the abdomen may be presumed to be due to the pressure of an excessive quantity of gas. Spastic constipation is much more often accompanied by pain than a sense of fullness: it can be recognized by the contracted condition of parts of the colon, the situation and degree of the spasm varying from one examination to another, and with more certainty by means of the X rays after a barium meal or a barium enema.

Intestinal flatulence may be due to the excessive production of gas in the intestines from excessive fermentation or putrefaction, retention of gas behind a faecal mass in constipation, the passage of some of the swallowed air into the intestines in severe cases of *aërophagy*, and deficient absorption of gas due to the impeded venous circulation in cirrhosis of the liver and heart failure. The stools should always be examined: if they are bubbly, acid in reaction, and contain obvious excess of vegetable residue, intestinal fermentation is probably the cause; if they are alkaline in reaction, have a putrefactive odour, and contain obvious fragments of meat, excessive putrefaction is probably present. On incubating some of the stool made thin with water for twenty-four hours in an apparatus in which the gas evolved can be collected, it is found that little or no gas develops and the stool remains neutral in reaction if there is no abnormal bacterial activity. When excess of gas is evolved, it is due to fermentation of carbohydrates if it is odourless and the stools have become very acid, and to putrefaction of proteins if it has an unpleasant odour of putrefactive products and the stool is very alkaline.

In the absence of excessive fermentation or putrefaction, a history of constipation would suggest that that is the cause of the flatulence (see CONSTIPATION, p. 158). *Aërophagy* only leads to intestinal flatulence when it is so well marked as to be easily recognized.

Arthur F. Hurst.

FUNGOUS AFFECTIONS OF THE SKIN.—We here include: (1) *Favus*; (2) *Ringworm*; (3) *Eczema marginatum*; (4) *Tinea imbricata*; (5) *Tinea versicolor*; and (6) *Erythrasma*.

1. **Favus** in man is due in about 99 per cent of cases to inoculation with the *Achorion Schönleini*. Four other achorions, of animal origin, of which that of the mouse, the *Achorion quinqueannum*, is the most important, have been identified, and it has been proved that the affection can be communicated from various animals to man, but the instances are so rare as to be negligible. Between the achorions on the one hand and the microsporons and trichophytos on the other (see below) there are close morphological resemblances, but the clinical differences are well marked.

Favus, while showing a distinct preference for the scalp, may attack any part of the skin (Fig. 262), and even a mucous membrane. The lesions—tiny sulphur-yellow discs with a cup-like depression in the centre, and in hairy parts pierced by a hair—resemble and are characterized by a peculiar mousy smell. The lesion begins as a collection of whitish material, somewhat resembling a pustule, which grows and presently becomes dry and friable. The cup-like disc can then be detached from the epidermis, leaving a pimply, smooth, greasy surface. As they grow, the discs often run together. In a later stage irregular crusts are formed, separated by pale, bluish-pink scars. The crusts, when broken up, are seen under the microscope to consist of spores, varying much both in size and shape, and of short threads of mycelium, which may penetrate into the mucous layer of the epidermis, and may even reach the derma; this rarely occurs in trichophytosis. Hairs affected with favus are discoloured and lustreless; they may fall out, but do not break off as in ringworm. Under the microscope one may see in favus-hairs segments of fungus 12–15 μ long, dichotomized at an acute angle, with groups of spores, irregular in size and shape, and often numerous air-bubbles. If the nails are affected, the ungual cells will be found to be separated by irregular threads of mycelium, or by spores.

In the less characteristic cases the lesions must be examined closely under a good lens for remains of the yellow discs of favus or the broken hairs of ringworm. If, owing to applications to the skin, the crusts are lacking, treatment should be stopped for a few days, when the whitish points and the discs will usually reappear. In prolonged cases the crusts may be replaced by an irregular, lumpy, dirty-yellowish accumulation, but the odour of favus will still remain. At this stage the disease may resemble *psoriasis* of the scalp; but there is a much greater loss of hair, the scales are less pearly, and even when no discs or sulphur-yellow scabs can be seen about the edges, the lustreless hair and the atrophic scarring left by the scabs are sufficiently distinctive of favus. The scarring may suggest *lupus erythematosus* of the scalp, but in that affection the crusting and the mouse-like odour are absent, while generally there are characteristic lesions on the face. From both *eczema* and *seborrhoea* favus is differentiated by the fact that its lesions are never diffuse, but always have a definite margin. In *alopecia areata* there is no scaling, crusting, or cicatrix.

2. **Ringworm**—whether of the scalp, the beard, the hairless skin, the mucous membrane, or the nails—is due to fungi belonging to two different families, the microspora and the trichophyta, each of them comprising a number of different species. In the one case the affection is styled *microsporiasis*, or *tinea* with small spores; in the other, *trichophytosis*, or *tinea* with large spores—the size of the spores, however, is not an absolute

Fig. 262. Favus: showing the very wide distribution over the body, as well as the scalp. (From Sir Malcolm Morris's "Diseases of the Skin".)

differentiating feature, as some of the trichophytons have small spores. Eleven species of microsporon ringworm have been identified; of the trichophyta, upwards of thirty. Only four species of the microspora, and the same number of species of the trichophyta, are of importance. The four microsporon are *M. Audouini*, *M. felinum*, *M. canis vel canosum*, and *M. equinum*; the four trichophytons, *T. crateriforme*, *T. acuminatum*, *T. sulphureum*, and *T. violaceum*. In both families some of the species are of animal origin, and it is these which account for the majority of the *inflammatory* forms of ringworm, including kerion.

Of the microsporon, the type species is *M. Audouini*, which is the cause of some 90 per cent of the juvenile ringworm of London. *M. felinum* and *M. canis*, closely allied species, are responsible for an appreciable percentage of human ringworms—the one in England, and the other in France. Of the four clinically important species of trichophytons, the one encountered most frequently is *T. crateriforme*; next comes *T. acuminatum*, then *T. sulphureum*, which, however, is not known in France; and lastly *T. violaceum*. A fifth species of trichophyton, *T. rosaceum*, which chiefly affects the beard, but also the hairless skin, is said to be relatively frequent in Northumberland and Durham.

The division of the ringworms into a small-spored and a large-spored group may easily lead to confusion in diagnosis, for among both microsporon and trichophyton the spores vary considerably in size, according to the species. Those of the microsporon may be as large as $4\ \mu$, while those of the trichophyton may be as small as $3\ \mu$; the limits of the one are 2 to $4\ \mu$, and of the other, 3 to $8\ \mu$. Clinically, therefore, microsporiasis and trichophytosis are to be differentiated from each other not alone by the size of the spores, but also by their shape and arrangement and cultural characteristics.

First, as to *shape*: In microsporiasis the spores are, speaking generally, round or ovoid; in trichophytosis, they tend to be square with rounded angles, or oblong with sharper angles. Still more important, for diagnosis, is the *arrangement* of the spores. In microsporiasis they are dotted about irregularly, and the mycelium interwoven with them is curved and branching, and irregularly jointed. In trichophytosis they are arranged in regular chains, and the mycelium is short and regularly jointed. In microsporiasis the fungus forms a greyish sheath around the hair—whether of the scalp or of the body—which it eats away, fraying the edges, penetrating to the interior of the shaft, and growing downwards towards the root. Presently the hair breaks off, at some distance from the follicular orifice, and the parasitic sheath is disintegrated and may be seen as a patch of ash-coloured scales on the epidermis. In trichophytosis, the parasite attacks the root of the hair first, and grows upward. The hairs are broken off short, and no sheath is to be seen outside the follicular orifice. Some small-spored trichophytons form a sheath outside the hair like that of microsporiasis, but the spores observe the chain-formation which is characteristic of trichophytosis, and this is never present in microsporiasis. These small-spored trichophytons are all pyogenic, and are the cause of many cases of kerion.

Trichophytons may be either *endothrix* or *endo-ectothrix*. If the parasite penetrates the hair between the cuticle cells and develops entirely within the hair-structure, it belongs to the endothrix class. If it develops not only within the hair, but also continues to proliferate in the follicle outside, it must be allocated to the endo-ectothrix class. The great majority of the cases of scalp trichophytosis are due to endothrix infections; but the endo-ectotriches are responsible for most of the ringworms of the hairless skin, for nearly all the adult ringworms, and for the majority of specially inflammatory cases.

In the case both of the microspora and of the trichophyta *cultures* may have to be grown to distinguish between the different species. *M. Audouini* gives rise to downy disc-shaped cultures with radiating furrows and a central boss. The species of animal origin yield large, exuberant cultures.

Of trichophyton cultures there are four main types: (1) The crateriform or acuminate; (2) Those with large white growths, either powdery or velvety; (3) The faviform; (4) A single species, *Epidermophyton inguinale*, which is the cause of eczema marginatum. In the first group, to which belong all four clinically important species, the culture resembles the crater of a volcano, white, cream, or primrose-coloured, or is like a mountain peak ('acuminate'), grey or yellowish in colour. The parasites of this

cultural group are all endotriches. In the second group the cultures are very large and white, some of them powdery, others velvety. The species which yield cultures of this type are all endo-ectotriches, and are of animal origin. The species which give cultures like those of the parasites of favus, although the clinical course of the lesions and the appearance of the fungus in the hair leave no doubt that they are trichophytons, are also of animal origin. The *Epidermophyton inguinale* yields a yellow-orange culture, dry and powdery, but often white and velvety as the result of pleomorphism.

Ringworm of the Scalp (Tinea tonsurans). Both the small-spored and the large-spored ringworm of the scalp begin as a small red papule which develops near the orifice of a hair-follicle: the size, and yet more the shape and arrangement of the spores, and the way in which the hair is attacked, help to distinguish between them. In trichophytosis there is a much smaller number of stumps to be seen with the naked eye: and on the surface of the scaly patches, among the remaining healthy hairs, one may detect those dark points to which the affection owes its name of 'black-dot ringworm'. These dots are broken or coiled-up hair-stumps. If the whole scalp is thus affected the case becomes one of 'disseminated ringworm'. In trichophytosis the scales are scantier, or may even be absent, and the outline of the lesions is not so rounded or so well defined. As a rule it is not difficult to distinguish *tinea tonsurans*, whatever its form, from other scalp affections, the clinical picture—the broken hairs, the black dots, the slight scalliness, the prominent follicles, the baldness, in varying degrees, of the involved area—being sufficiently distinctive. In *favus* there is the same dull and brittle condition of the hair, but the patches are not generally circular, while in ringworm the cup-shaped crusts are absent, there is no mousy smell, nor is the skin atrophic. The broken hairs distinguish *tinea tonsurans* from *pityriasis* of the scalp and from *psoriasis* of the hairy skin, in both which affections the hairs fall out unbroken. In *psoriasis*, too, there is a greater degree of scalliness, generally it is not the scalp only that is affected, nor is loss of hair usual, though it occurs sometimes. In the anomalous form of ringworm known as *tinea decalvans*, or bald ringworm, in which the hair falls out in places leaving smooth bare patches, confusion with *alopecia areata* may be avoided without much difficulty: the billiard-ball smoothness of the patches in the latter condition is not present in ringworm. Another differential feature is the shape of the short hairs found at the edge of the patches: in *tinea tonsurans* they are bent, whereas in *alopecia areata* they may be compared to a note of exclamation. In the latter condition, too, the hairs that remain are free from fungus. In the infrequent cases of inflammatory ringworm, a condition somewhat resembling *impetigo* or *eczema* may be set up: but the broken stumps and the limited area of the disease, together with the history of the case, should prevent confusion with those affections. *Seborrhœa* can be ruled out by remembering the greasiness of the scales, the diffusion of the condition over the whole scalp, and the absence of patches of baldness.

Ringworm of the Beard (Tinea sycosis). From ordinary *sycosis* this affection is distinguishable by its more rapid spread, and the greater lumpiness of the affected surface. In *sycosis vulgaris*, too, the pustules are usually pierced by a hair, and are quite small, and unless there is much more suppuration than is usual the hairs do not fall out. *Tinea sycosis* differs from *eczematous folliculitis* in the absence of the serous discharge that marks the latter affection. In the *eczematous* condition, again, there is but slight if any loosening of the hairs. The affection is not confined to the hairy parts, as in *tinea sycosis*, nor do the patches assume the ring-like form. The ring-formation is absent also in *seborrhœa*, nor is the hair involved as in beard ringworm. In the *circinate tubercular syphiloderm* the border of the lesion is darker and more infiltrated, and there is either atrophy or pigmentation, or both. Occasionally the severer cases of ringworm of the beard take the form of a single tumour-like formation which may be mistaken for a *carbuncle*, but the inflammation is almost always less active than in *carbuncle*, and the swelling, pain, and pyrexia are correspondingly less. In any clinically doubtful case, examination of the hairs under a microscope will show whether or not the case is one of beard ringworm by revealing the presence or the absence of the trichophytic fungus.

Ringworm of the Body Skin (Tinea circinata). The small, red, slightly raised spot which is the first visible lesion of ringworm of the body, gradually spreads at the edge and becomes scaly. Fading away at the centre, the redness leaves a slightly discoloured branny area which forms the inside of a red ring. The circle slowly enlarges without any

widening of the edge. Usually, though not always, there are several rings, sometimes, though seldom, arranged concentrically, and those adjoining each other may run together. Frequently, as the edge advances, there is no involution in the centre, the lesions then appearing not as rings but as patches. A similar appearance may be produced by the local application of a skin irritant such as *carbolic acid*, but with the latter the hairs show no trichophyta on microscopical examination.

In *eczema seborrhæicum* the scales are greasy, and often there are projections into the glandular openings. In *psoriasis* the skin is affected in ring-like areas, but all the other characters are different. From the *circinate tubercular syphiloderm*, ringworm of the body may be distinguished in the same way as ringworm of the beard (see above). As a rule microscopic examination will disclose the ringworm fungus—usually a trichophyte—without difficulty; but occasionally the parasitic elements are deep-seated, and must be sought in a section of the affected tissue.

Ringworm of the Nails (Onychomycosis) may appear in association with trichophytosis of the beard or of the body skin, but usually occurs as a separate affection. The first visible lesion shows as a greyish stain under the borders of the nail and at the root. Inflammation of the matrix follows and the structure of the nail degenerates, becoming thickened, spongy, and more or less brittle, with a dulled surface. When exfoliation occurs, a mass of disintegrated nail substance is seen, in which the fungus may be found.

Similar changes may arise in connection with gout, rheumatism, and other constitutional disorders—those for instance in which there is impaired nutrition—as well as in such inflammatory affections as *eczema* and *psoriasis*. From all such cases the presence of the parasitic elements will suffice to differentiate onychomycosis. In the onychomycosis of *favus*, the stains under the borders of the nail are yellower, and the mycelial elements shorter and less regular.

3. Eczema Marginatum.—In this form of ringworm of the body, more frequent in tropical climates than in Europe, the parts attacked chiefly are the lower portion of the abdomen, the groins, the buttocks, the fold of the nates, and the axillæ—parts, that is, where the skin surfaces are in contact. The hands and fingers, the interdigital spaces between the toes and the dorsal surfaces of the toes, the nails and the soles may also be affected. The hair is never involved. The characteristic feature of the lesions on the body is their well-defined scaly margin. They are often *eczematoid*, but they can be distinguished from *eczema* and from *eczema seborrhæicum* by their gradual spread and broad, elevated margin and by the ring-like formation of the early stage. Between the toes they occur as patches of white macerated skin. If any doubt remains, the microscope will clear it up by revealing the parasite, the *Epidermophyton inguinale*.

From *eczema marginatum*, *dhobie's itch* is differentiated very imperfectly. It is in fact a popular name for all epiphytic skin diseases of warm climates, but usually it connotes diseases of this group of which the sites are the inguinal regions and the axillæ. Castellani distinguishes two fungi as the cause of *dhobie's itch*, besides *Epidermophyton inguinale*, namely *E. Perneti* and *E. rubrum*; and Manson holds that, in many cases, the parasites concerned are *Microsporon minutissimum* and *M. furfur*. For practical purposes, *dhobie's itch* may be regarded as another name for *eczema marginatum*.

An ulcerative dermato-onychosis occurring in Ceylon and the Malay States has been described by Castellani; sharply defined ulcers, nodules, and furuncles occur in various parts of the body as well as in connection with the nails, and are caused by a fungus which has been termed *Accladium Castellani*.

4. Tinea Imbricata.—known also as Tokelau ringworm was formerly peculiar to certain oceanic tropical climates in the East, but now has a wider distribution. Castellani recognizes four species of fungus causing the disease, *Endodermophyton indicum*, *E. tropicale*, *E. concentricum*, and *E. Mansonii*. The affection to which they give rise is characterized by a concentric arrangement of closely-set rings of scaly epidermis. The conditions from which this disease has to be distinguished are *tinea circinata* and *ichthyosis*. From the former it is differentiated by the greater abundance of the fungus elements, the tendency of the process to spread centripetally, the absence of marked inflammation or congestion of the rings, their concentric disposition, and the greater size of the scales. From the latter, by the presence of the fungus, the concentric arrangement of the scales, and the fact that the attached border of each scale is towards the periphery, the

free border being towards the centre of the circle, or group of circles, to which the scale belongs.

5. **Tinea Versicolor**—often styled pityriasis versicolor—is caused by the *Microsporon furfur*. The disease is contagious, but only in a low degree. The lesions, confined to the horny layer of the epidermis, take the form of roundish, scaly patches, with a definite margin, and of a colour varying from fawn to liver—in coloured races, grey or white: in persons who have lived in warm climates it may be black. The hair is not affected, nor are the hands and feet. As a rule the lesions are limited to the trunk, particularly the front of the chest, but occasionally they extend to the upper parts of the limbs: they have been mistaken for secondary syphilides, but the colour and distribution, and the large patches in which they are found, should serve to obviate the confusion. In exceptional cases the face may be invaded, and the affection might then be confounded with chloasma. From *pityriasis rosea* and from *eczema seborrhæicum* it may be distinguished by the absence of inflammatory reaction, except in persons who perspire freely. The lesions of tinea versicolor offer some resemblances to the pigmentary patches sometimes met with in *leprosy* and other diseases accompanied by pigmentation: but from these, as from the other cutaneous manifestations mentioned, they may be differentiated almost certainly by the ease with which the scales can be detached by a stroke of the finger-nail, and quite certainly by the fungous elements which may be detected microscopically in the scales after these have been treated with potash. The spores are rounded and, like the mycelium, have a double contour with a diameter of 3 to 5 μ : they are generally grouped together in masses, suggesting a resemblance to bunches of currants.

6. **Erythrasma**, due to the *Microsporon minutissimum*, presents several points of resemblance to *tinea versicolor*. In both it is only the horny stratum of the epidermis that is affected, nor is the hair ever attacked. In both there is but a low degree of contagiousness. The lesions offer some likeness to those of tinea versicolor, but they are reddish-brown in colour, and their usual site is the genito-crural region or the axillæ or both, though occasionally, in fat subjects, there may be extension to the abdominal and submammary folds and those of the large joints. In rare cases, erythrasma resembles one type of *eczema marginatum*, but is distinguished from that affection by its low degree of contagiousness and slow evolution, and by the absence of inflammation, which also distinguishes it from *eczema seborrhæicum* and from *pityriasis rosea*. Any doubt between erythrasma and any other affection, including tinea versicolor, may usually be cleared up by examination of a preparation under a microscope of sufficiently high power. The spores of *M. minutissimum*, like the threads of mycelium, are extremely minute, having a diameter of about 0.6 μ . The mycelial threads, of the same diameter, are so abundant and so twined together as to form, here and there, a network over the epidermic cells.

Ernest Dove.

GAIT, ABNORMALITIES OF. As a genuine aid to diagnosis the gait cannot be of much real assistance. There are, however, several diseases and affections which produce manifest, and in some cases peculiar, alterations in gait. In some respects, indeed, the gait is a diagnostic point in identity, though this probably also depends on the total back or front view of the individual, rather than on real peculiarities of gait as such.

In analysing gait for diagnostic purposes, we find that it consists of co-ordinate and painless movements of the muscles of the lower limbs and pelvis—often, indeed, sinking into purely reflex, or at least subconscience, movements—and these are associated, in easy and ordinary walking, with rhythmical movements of arms, body, and head. The directions, therefore, in which it can be disordered are: (1) *Inco-ordination*; (2) *Local loss of power*; (3) *Pain calling attention to the movements*.

1. **Inco-ordination.** The test for the presence of this is the complaint of the patient that he feels unsteady in walking, especially on turning or walking on uneven ground, or on walking or standing with the eyes shut: and if co-ordination only be at fault, it will then be found that on testing the legs for simple movements, such as flexion and extension, the power of the muscles is unimpaired. Having discovered inco-ordination, the next question is, to what may this be due? *Tabes dorsalis*, *ataxic paraplegia* (combined lateral and posterior sclerosis), *disseminated sclerosis*, *multiple neuritis*, and *hereditary ataxy* (Friedreich's disease) are far and away the commonest causes, in the order of mention: their differential diagnosis depends on many other symptoms and signs, discussed

elsewhere. *Cerebellar disease* causes rather a reeling in the gait than a simple inco-ordination in the individual movements: and here again other symptoms will be to the front. Localized *paralyses of eye muscles* may also cause inco-ordination: this will probably cause complaints of double vision, and may be diagnosed by the fact that the patient walks better with one eye shut than with both open—in cases of some duration it is quite likely that this simple test will not discover which is the affected eye.

2. Local Loss of Power is well illustrated by the waddling gait of *pseudo-hypertrophic paralysis*, calculated to get the weight of the body as speedily as possible on the foot as a basis. The diagnosis depends on the peculiar way in which the patient climbs up himself (see PARAPLEGIA, p. 621). Another condition in which the loss of power is due, not to the muscles themselves, but to the position of their attachments, is seen in *congenital dislocation of the hips*: the gait here, too, is waddling, the lower part of the back exhibits extreme lordosis, and the belly is thrown forward through attempts to balance the pelvis on the loose supports at the hips.

Other forms of local loss of power betray themselves by a limp or by a dragging of the foot or leg, and (or) peculiar positions of the feet, and possibly by wasting of muscles generally or locally: measurements must of course be made if wasting be suspected. *Infantile paralysis*, and *old hemi- or mono- or para-plegias* are the common causes of this, if it be unassociated with pain, and inquiry must be made as to mode of onset and duration, in completing diagnosis.

3. Pain on Walking is at once obvious, because complained of by the patient: acute inflammatory troubles of muscles, joints, or tissues will be obvious on examination, and chronic joint troubles, osteo-arthritis, etc., may be discovered easily, chronic gonorrhœa or pyorrhœa alveolaris not being forgotten as possible causes of these. One thing that may escape observation is hip-joint disease, when pain in the knee may be the complaint.

The only other caution we can administer here is to warn practitioners against any hasty conclusions as to the nature of a disease from the gait: the high-stepping gait of tabes, the shuffling gait of lateral sclerosis, the festinating gait of paralysis agitans, are all easy enough of recognition when a diagnosis is made, but are too frequently absent or atypical to allow much diagnostic superstructure to be built on them alone.

E. Farquhar Buzzard.

GALL-BLADDER ENLARGEMENT.

Physical Signs.—The only physical method of examination which is of material assistance in detecting enlargement of the gall-bladder is palpation: inspection, percussion, and auscultation seldom help. On careful palpation one may feel an oval, smooth swelling, which may be no larger than a hen's egg, or as big as a swan's, moving downwards close behind the anterior abdominal wall when the patient inspires, descending further from beneath the right costal margin near the tip of the ninth rib, or approaching the under surface of an enlarged and palpable liver in the right nipple line. The tumour generally extends inwards as well as downwards as it grows, so that it may ultimately cross the middle line below the level of the umbilicus. It may be large enough to be palpable bimanually in a thin patient: but it seldom fills out the loin in the way that a renal tumour would. It may or may not be tender, according as the cause of the enlargement is associated with inflammation or not: it feels firm and tense rather than hard: on careful percussion it may be found to give an impaired note, but it is seldom quite dull unless it is very big.

Diagnosis from other Swellings. It has to be distinguished particularly from four groups of conditions which may simulate it: (1) From *carcinoma* arising in the bile-ducts or gall-bladder, and replacing the latter with new growth; (2) From *tumours* in or attached to the liver in the neighbourhood of the gall-bladder, Riedel's lobe, secondary new growth, or more rarely gumma, abscess, or hydatid cyst; (3) From *movable kidney* or *hydronephrosis*; (4) From *tumours in organs in the neighbourhood*, such as carcinoma of the pylorus, carcinoma of the duodenum, carcinoma of the transverse colon, carcinoma or sarcoma of the right suprarenal capsule or right kidney.

1. Carcinoma of the Gall-bladder.—It may be difficult to decide whether a given mass is merely an enlarged gall-bladder, or a growth replacing the latter: in either case there may be a history of gall-stones, with biliary colic, pyrexia, and even jaundice, extending

over years; for primary new growth of the gall-bladder is often associated with gall-stones. The rapidity of the enlargement in the absence of any definite cause may suggest growth, particularly in a person of the cancer age; careful palpation may show that the mass is not smooth as most gall-bladder enlargements themselves are, but more or less nodulated or covered with bosses or irregularities, which in themselves suggest new growth, though similar bosses may be caused by projecting gall-stones; in some cases there may be secondary deposits in the liver, and sometimes the enlargement of the left supraclavicular gland points to malignant disease with metastasis. Notwithstanding these points, however, the differential diagnosis may be so difficult that laparotomy will be resorted to in order to decide it.

2. *The Tumours attached to or in the Liver.*—Those most likely to be mistaken for enlargement of the gall-bladder, or vice versa, are Riedel's lobe, secondary carcinoma or sarcoma of the liver, and much more rarely gumma, abscess, or hydatid cyst. A *Riedel's lobe* (see p. 461) may be quite impossible to distinguish by physical examination from an enlarged gall-bladder or from a movable kidney. Owing to the absence of symptoms there is seldom need for laparotomy; but sometimes the lobe arouses such alarm lest it be some more serious condition that laparotomy may be resorted to and the diagnosis verified in that way. Speaking generally, a Riedel's lobe usually depends from the liver farther to the right than a gall-bladder does, and it is more apt to simulate an enlarged or a movable kidney than an enlarged gall-bladder.

Secondary new growth in the liver, whether carcinoma or sarcoma, nearly always causes very considerable, and sometimes enormous, enlargement and great hardness of the organ, not infrequently associated with JAUNDICE (p. 405), ASCITES (p. 59), or both. The diagnosis depends, first, upon the discovery of a primary growth, which in the case of carcinoma is likely to be in the stomach, duodenum, pancreas, colon, or rectum; or in the case of sarcoma, the eye—some of the greatest enlargements of the liver being due to secondary deposits of melanotic sarcoma, sometimes a great many years subsequent to the removal of the primary ocular growth; and secondly, on the discovery in the liver of several separate nodules, some of which may be felt to be umbilicated, that is to say depressed in their central part and raised around the edges.

Gumma of the liver is not very frequent nowadays, and when it occurs is apt to be mistaken for new growth unless there is an obvious history of syphilis or the effects of tertiary lesions are visible elsewhere, especially gummatous lesions of the skin or leukoplakia of the tongue. The diagnosis may be confirmed by obtaining a positive Wassermann's serum reaction, or by the beneficial effects of giving salvarsan, or potassium iodide and mercury, though these drugs do not always cause a gumma of the liver to disappear rapidly. In cases that have come to laparotomy the diagnosis between gumma and new growth is by no means easy even when the liver is inspected.

Abscess of the liver (see p. 464), if it is to simulate an enlargement of the gall-bladder, is likely to be a single large one, which if it has not arisen in some pre-existent mass, such as a gumma, new growth, or hydatid cyst, is likely to have been acquired in a tropical country, where the patient may have suffered from amebic dysentery. The diagnosis may not be evident until laparotomy is resorted to, or until the mass is punctured with an exploring needle, when the chocolate-and-milk appearance of the pus obtained may be characteristic.

Hydatid cyst of the liver is seldom situated in such a position as to cause difficulty of diagnosis from gall-bladder enlargement, the cyst being more often embedded in the liver substance, or projecting from its upper surface. The diagnosis might be arrived at if the patient were known to have had hydatid cysts elsewhere; but in most cases it is only when laparotomy has been performed that the correct diagnosis can be made. It might have been suggested by the occurrence of eosinophilia, and also by a specific hydatid serum reaction, though neither of these is likely to be found unless the hydatid cyst has produced toxic symptoms, because latent hydatid cysts cause no symptoms.

3. *The Distinction between an Enlarged Gall-bladder and a Movable Kidney or Hydronephrosis.* This might seem to offer no difficulty, but clinically it is not always easy. There is often no jaundice to suggest gall-bladder trouble, nor need there be any obvious urinary changes to suggest kidney, so that the diagnosis has to be made chiefly by palpation. One would lay stress upon the fact that the gall-bladder is more

easily felt anteriorly than posteriorly, whilst the reverse is the case with the kidney : that the kidney is the more freely movable of the two, as a rule ; that it is seldom possible to demarcate the upper pole of an enlarged gall-bladder in the way that the top of a movable kidney can sometimes be made out ; that with a kidney tumour the loin is dull, whilst with gall-bladder enlargement it is resonant ; and that, on rather firm bimanual palpation the peculiar sickening sensation that the patient may complain of is more characteristic of kidney than it is of gall-bladder.

4. *Tumours of other Organs simulating Enlargement of the Gall-bladder* have to be distinguished partly by the fact that new growths of the pylorus, duodenum, transverse colon, or suprarenal capsule, big enough to simulate an enlargement of the gall-bladder, will seldom have the smooth oval outline that the latter nearly always possesses. There may, however, be distinct symptoms attributable to the primary growth, such as dilatation of the stomach, coffee-ground vomit, achlorhydria, or there may be secondary deposits in the liver, in the left supraclavicular gland, or elsewhere, to indicate the diagnosis. It is not easy, however, to exclude enlargement of the gall-bladder without resorting to laparotomy in some of these cases.

The Cause of Enlargement of the Gall-bladder. Having decided that a given tumour is an enlargement of the gall-bladder, it is necessary to determine to which of the following causes it is due : —

Empyema of the gall-bladder	Typhoid fever;
Chronic pancreatitis	Obstruction of the common bile-duct by a
Carcinoma of the head of the pancreas	gall-stone
Cholecystitis from : (i) Gall-stones ;	Obstruction of the cystic duct by gall-stone
(ii) New growth	Simple mucocele.

It is noteworthy that *gall-stones* lead to enlargement of the gall-bladder far less often than might be expected ; if the inflammation they lead to, and which leads to them, does not go on to empyema of the gall-bladder, the latter usually becomes thick-walled, contracted, and embedded in dense adhesions, the latter preventing it from dilating even when the cystic or common bile-ducts become obstructed by a stone. It is the exception to find a very big gall-bladder with gall-stones. Indeed, in a middle-aged patient in whom there has not been any very definite attack of biliary colic, the occurrence of progressive and considerable enlargement of the gall-bladder, associated with a deepening jaundice and no ascites, should always arouse serious suspicion of there being a *lesion of the head of the pancreas* which has extended along the pancreatic duct so as to occlude the common bile-duct gradually, the commonest cause of these symptoms being either *chronic pancreatitis* or *carcinoma* of the head of the pancreas. The greater the epigastric pain in such a case, especially if it is paroxysmal and such as to suggest gall-stones, the more likely is the lesion to be chronic pancreatitis rather than new growth, and the suspicion may be confirmed by CAMMIDGE'S PANCREATIC REACTION (p. 128). There are, of course, cases in which gall-stones are the cause of the enlargement ; but when this is so there is nearly always tenderness over the gall-bladder, and pain when it is palpated firmly, associated with a rise of temperature, possibly with rigors, especially if the inflammation has spread to the bile-ducts (infective or suppurative cholangitis). Leucocytosis, with a relative increase in the polymorphonuclear cells, would indicate that in addition to gall-stones there is suppurative inflammation—that is to say, *empyema of the gall-bladder*—requiring surgical treatment.

Another important cause for empyema of the gall-bladder is *typhoid fever*. The diagnosis is not difficult as a rule, for there will be no question of new growth or of gall-stones in most of the cases, and the patient will have been suffering from a prolonged asthenic fever which will have been diagnosed already by Widal's test. In a certain number of typhoid patients rapid enlargement of the gall-bladder occurs owing to the bacillary infection, and there are instances in which the distention has become so great that the gall-bladder has ruptured spontaneously and produced general peritonitis. Sometimes the inflammatory products discharge themselves naturally by the bile-passages ; but it is often necessary to open and drain the gall-bladder, the diagnosis of the nature of the empyema being settled by bacteriological examination of its contents. It is noteworthy that, whereas in uncomplicated cases of typhoid fever Widal's reaction rapidly becomes negative during convalescence, when there are persistent bacillary complications

the serum test may remain positive, or at least partly positive, over much longer periods. When an empyema of the gall-bladder due to typhoid fever remains latent for weeks or longer the nature of the case may be suggested by the previous history, and by the persistence of the positive serum reaction.

Simple mucocele of the gall-bladder is probably the result of former catarrh of the cystic duct, or of a gall-stone which has disappeared; in many cases it may be impossible to determine the precise cause; the gall-bladder may become greatly distended with perfectly colourless mucoid fluid, free from bile pigment, though sometimes containing crystals of cholesterin (*Fig. 263*). The fluid is sterile. There are usually no symptoms; the patient may by chance have discovered the tumour for herself. Such a mucocele may be mistaken for a movable kidney, and the diagnosis of the nature of the mass is sometimes obscure until operation is resorted to.

GANGRENE. When any necrotic tissue becomes infected with moulds or putrefactive micro-organisms, the resulting condition is known as gangrene dry, moist, or spreading. (See also GANGRENE OF THE LUNG, p. 322.)

CAUSES OF GANGRENE.

Local Traumatic Causes:—

Severe bruising or crushing of the tissues
Prolonged pressure—splint-sores, bed-sores
Extreme heat or cold—burns, frostbite, etc.
The action of strong chemicals—acids, alkalis, phenol, etc.
The action of powerful electric currents, or of lightning.

Lowered Vitality of the Tissues, either (a) Local, or (b) General.

Local: adjacent to the infected area in such acute infections as—

Septic wounds	Gonorrhœa	Scarlet fever
Erysipelas	Syphilis	Cancerum oris.
Anthrax	Diphtheria	

General: occurring after some slight injury, as a complication or sequela of—

Diabetes	Measles	Yellow fever
Enteric fever	Infantile marasmus	Malaria
Small-pox	Cholera	Poisoning by snake-venom.
Chicken-pox	Plague	

Disturbances of the Innervation of the Tissues, such as occur in—

Raynaud's disease	Tabes dorsalis	Meningo-myelitis
Erythromelalgia	Leprosy	Lesions of the spinal cord and cauda equina.
Peripheral neuritis	Hemiplegia	
Syringomyelia	Myelitis	

Stoppage of the Circulation, due to

Embolism	—Ligature, tight band-	The arterial spasm of
Thrombosis	ages, splints; Pressure	ergotism, the so-called
Endarteritis; senile	of new growths; Pres-	'epidemic gangrene'
gangrene	sire of aneurysms or	The after-effect of poison-
Occlusion of vessels,	effused blood	ing by coal-gas or carbon
complete or partial, by		monoxide.

Speaking generally, more than one of the causes enumerated above will be at work in the production of gangrene in any particular instance. Thus, in the gangrene following severe injury to one of the extremities, stoppage of the circulation through the affected part is usually observed in addition to the direct injury caused by the mechanical crushing of its tissues. Again, in *cancerum oris* or *noma*—the name given to the spreading gangrene

of the soft tissues of the mouth and cheek occurring in debilitated children after measles or scarlet fever—great feebleness of the circulation contributes to its production, in addition to the lowered vitality of the necrotic tissues (*Fig. 95*, p. 95). A diabetic patient with gangrene may owe it partly to the impoverished or altered quality of his blood, partly to the arteriosclerosis that is often associated with diabetes, and partly to peripheral neuritis occurring as a further complication of his disease.

In *dry gangrene*, or *mummification*, the affected part of the body, usually the distal end of a limb, becomes livid and cold, and gradually blackens as the blood-pigment diffuses out of the blood-corpuscles and enters the tissues; the part withers as the fluid in it evaporates. It is a slow process; putrefaction is little in evidence, and there is no markedly offensive odour about the part, for it is too dry to afford a satisfactory culture medium for the bacteria of putrefaction; between this dry gangrenous tissue and the adjoining healthy part of the limb is an inflammatory zone, the line of demarcation. Dry gangrene is common in cases of embolism or other complete obstruction of the arteries, in senile gangrene (*Fig. 264*), and in Raynaud's disease (*Fig. 265*); the affected part is converted ultimately into a shrunken, black, and mouldy-smelling mass.

Fig. 264.—Gangrene of the foot. Note the line of demarcation at *a*. (From '*An Introduction to Surgery*', by kind permission of Prof. Rutherford Morrison.)

Moist gangrene, *sphacelus*, or *sloughing*, may often be seen after severe crushing of a leg or an arm, when the distal portion of the limb dies and putrefies. At first hot, red, and painful, the crushed extremity presently becomes mottled, purplish, and cold, as the circulation through it stops. Putrefaction soon appears in the dead tissue, the skin rising into discoloured blebs, which, on rupture, give issue to offensive sanious fluid. A dusky red line of demarcation separates the gangrenous from the adjoining healthy part. 'Sloughing' is the name commonly given to the putrefactive separation of smaller parts of the soft tissues from the body; sloughs are the localized gangrenous patches that result from most of the injuries described under the first heading.

Spreading gangrene is the form due to infection by special virulent bacteria, generally anaerobic, such as *Bacillus aerogenes capsulatus*, which cause death of the tissues in which they grow and spread. Fatty acids, sulphides, and gases are among the chemical compounds formed by these micro-organisms, and it is to them that the offensive odour is due.

Fig. 265.—Symmetrical gangrene of the fingers in Raynaud's disease. (Reproduced by permission of the House Committee of St. George's Hospital from a water-colour drawing by the late Dr. E. A. Wilson.)

THE DIAGNOSIS.

Traumatic Local Causes and Lowered Vitality of the Tissues.—Gangrene being a massive necrosis of some part of the body, producing changes obvious to the eye and nose, the fact of its occurrence can rarely be difficult to determine. The history of exposure to one or another of the forms of severe injury or infection, or of exposure to some injury or infection that would be unimportant if it occurred in a healthy person, but may lead to gangrene in severely debilitated patients, ought to be elicited readily.

Disturbances of the Innervation of the Tissues. Gangrene due to disturbances in the innervation of the tissues is commonly described as a trophoneurosis or trophic change. It may be either *chronic* or *acute* in its onset.

Gangrene of a Chronic Type. In *Raynaud's disease* gangrene may affect the tips of the fingers or the toes, less often the edges of the ears and the end of the nose or tongue. It is often symmetrical, and is preceded by the other two well-known stages of the disease, namely, local syncope, in which the affected extremities become cold, numb, and white; and local asphyxia (*Fig. 266*), in which they turn from white to blue-grey or purple. Rarely Raynaud's disease is characterized only by recurring attacks of necrosis in the extremities with deformity as the result of repeated tissue loss. It is a chronic affection, and gangrene only occurs in marked cases and in their later stages, although it may be seen at any age. As a dry gangrene attacking the superficial and terminal parts of some

Fig. 266.—Raynaud's disease : stage of local asphyxia.

of the digits, it may bear some resemblance to *senile gangrene*; this, however, generally attacks only one limb, usually a foot; it is more extensive and progressive than the gangrene of Raynaud's disease; and it is associated with well-marked disease of the arterial walls.

Gangrene may be a part of the manifestations of *erythromelalgia*, a rare and chronic disease of adults who do hard work while exposed to considerable changes of temperature. It is characterized by pain, heat, and flushing of one or more of the extremities, all aggravated when the limb is allowed to hang downwards. The colour varies from rosy red to purple, and the affected parts are hot: hence the condition should not be confused with Raynaud's disease.

The gangrene of *erythromelalgia* is confined to the extremities and may be symmetrical; as a rule it is more narrowly localized and less superficial than the gangrene met with in Raynaud's disease.

Gangrene is a rare complication of *peripheral neuritis* due to alcoholic, arsenical, or other forms of poisoning: it occurs only in patients exhibiting the vasomotor type of neuritis. This closely resembles Raynaud's disease, with which, indeed, some hold that it is identical. The gangrene is symmetrical; the patient will very probably exhibit other symptoms of peripheral neuritis—disturbance of sensation, tremor, paresis, wasting, trophic changes—and a history of alcoholic excess may be obtainable.

Gangrene of the skin and superficial tissues of the hands or feet, or of the finger-ends, may be met with in *syringomyelia*; this disease, if associated with painless whitlows on the fingers, is known as *Morcan's disease*. This gangrene is to some extent traumatic, and may be symmetrical; but the diagnosis should not be difficult, for in most cases three prominent symptoms are seen in syringomyelia: (a) Loss of the sensations of pain and of temperature, tactile sense being preserved over the anæsthetic area—the 'dissociated anæsthesia' of Charcot. (b) Trophic changes about the extremities, often originating in some neglected or unnoticed injury; hypertrophy or atrophy of the skin or nails; trophic changes in the joints, the so-called 'Charcot's joints': brittleness of the long bones, with a tendency to spontaneous fracture. (c) Progressive muscular atrophy, invading the hands first, later the forearms, arms, and shoulders; atrophy of the spinal muscles may ensue, giving rise to spinal curvature. Thus the gangrene of syringomyelia is characterized by its painlessness, and by its combination with other well-marked special

symptoms: in addition the hands often present certain deformities, 'CLAW-HAND' (p. 141) resulting when the muscular atrophy of the hands is marked, 'succulent hand' when much hyperplasia and redundancy of the soft parts of the hand and fingers occur.

Gangrene of the toes may occur in *tabes dorsalis*, usually in connection with a perforating ulcer about the ball of the big toe (*Fig. 666*, p. 893). The process is slow and painless, not symmetrical: and is associated with the other main signs of tabes (p. 753). Gangrene of a similar sort, and similarly started by some ulceration or a neglected injury, is common in *leprosy* of the smooth or anæsthetic type. It occurs only in the later stages of this disease, and from its rarity calls for no further consideration here.

Gangrene of an acute type, attributable to trophic changes, occurs in the form of *decubitus acutus*, or *acute bed-sore*, in certain acute disorders or infections of the central nervous system or spinal cord producing both paralysis and anæsthesia. Within a few days or even hours of the primary lesion, secondary changes are seen in the skin and soft tissues where they are most exposed to pressure—about the buttock, sacrum, coccyx, iliac crest, great trochanter, tibia, or heel, according to the position in which the paralysed patient lies. When the pressure is unduly great or protracted the skin turns red or purple, and unless most carefully protected presently undergoes extensive and spreading necrosis and gangrene. Hot-water bottles that would expose an ordinary patient to no discomfort or danger, may set up necrosis and gangrene if allowed to remain too long or too closely in contact with the skin of a paralytic patient liable to the formation of bed-sores. The prolonged application of an ice-bag may do the same: indeed, the use of ice-bags over long periods may be followed by gangrene even in patients who are free from any nervous disorder, and particularly in patients who are very fat. The chief nervous lesions in which the acute bed-sore is seen are the following: *hemiplegia*, whether due to cerebral embolism, hæmorrhage, or thrombosis: acute infections of the spinal membranes or cord, such as *meningitis*, *myelitis*, or *meningo-myelitis*, whatever the nature of the infection: *transverse lesions* of the spinal cord or cauda equina, such as are caused by fractures or fracture-dislocations of the spinal column, or by penetrating wounds involving the spinal cord. These bed-sores occur only in the anæsthetic areas, and hence tend to escape the notice of the patient, who may also be unconscious or delirious. It is most important to keep a sharp look-out on the skin over all the bony prominences exposed to pressure in these patients, so that an incipient bed-sore may be detected at once, and its spread checked by suitable treatment. Once well established, the acute bed-sore tends to spread in area and in depth in spite of the most careful treatment, and brings about the death of the patient by septic absorption, pyæmia, or the exhaustion consequent to prolonged suppuration.

Stoppage of the Circulation. Among the most important and extensive causes of gangrene are those in which the exciting factor is some more or less complete vascular obstruction, with consequent stoppage of the circulation, and the death of those tissues whose blood-supply is cut off. Occlusion of arteries is more important than that of the veins, but in exceptional cases moist gangrene of some distal part follows blocking of the veins by thrombosis or by pressure from without, while the arteries are still patent. The importance and amount of the pathological changes following vascular obstruction depend on the extent to which collateral channels are able to carry on the circulation through the affected area. If they are ill-developed, the consequences of the stoppage are serious. *Embolism* is likely to occur in patients who have valvular disease of the heart, with vegetations on the mitral or aortic valves that may be swept off into the blood-stream: or the embolus may be derived from a blood-clot formed in a diverticulum of one of the chambers of the left heart, or in an aneurysm, or upon the surface of a rough atheromatous aorta. *Thrombosis*, whether arterial or venous, may be suspected in patients in whom no source for an embolus can be detected, but who exhibit widespread arterial degeneration, phlebosclerosis, or local disease that may spread to some vessel and set up clotting in its contents. The occurrence of arterial embolism, in the leg for example, is marked by a sudden and very severe pain in the limb about the level of the blockage. The parts beyond become numb, cold, insensitive: pulsation can no longer be felt in the arteries distal to the obstruction. The gangrene that follows is usually of the dry type. Very similar symptoms may mark the occlusion of an artery in the leg by thrombosis, but the onset is usually much more gradual, and the pain may be terribly protracted and severe.

Senile gangrene occurs in patients of advanced years with extensive arterial sclerosis : in many instances they also give a history of gout, or suffer from diabetes mellitus. It is in reality a form of occlusive gangrene, due either to the clotting of blood on the diseased and roughened arterial intima, or to increasing obstruction of the arterial lumina by a proliferative endarteritis. It is often of insidious onset and confined to one lower limb, just as embolic gangrene may be : but it tends to spread upwards slowly and indefinitely, a tendency that finds a natural explanation in the extensive character of the arterial degeneration that goes with it. It is not often symmetrical : if more than one limb is affected, the lesions are successive in their development.

Little need be said about the gangrene that follows complete or partial occlusion of the vessels by the other causes enumerated above. The gangrene will be secondary to some primary lesion that will seldom fail to be obvious. The *ligature of an artery* in the course of a surgical operation of the femoral, for example, in the treatment of popliteal aneurysm has caused gangrene of the leg in patients whose collateral circulation unfortunately proved to be inadequate. The application of *tight bandages* round a limb, possibly to check hæmorrhage, may cause similar gangrene if they are left on too long. *New growth* readily compresses or invades veins, or arteries in exceptional cases, and renders them impervious : in either case gangrene of some distal part may result. The new growth may be primary, or a secondary deposit growing perhaps in a lymphatic gland. Thus carcinoma in the mammary gland, or endothelioma of the lung or pleura, may lead to secondary deposits about the axillary and subclavian vein and artery : and these may be so extensive as to obstruct the circulation through the arm, and set up moist gangrene in the fingers. Similar gangrene of the fingers may result from the vascular obstruction caused by a large intrathoracic *aneurysm*, or by *blood* that has escaped and clotted round the vessels of the arm.

The *epidemic gangrene of ergotism* is only of historic interest in Great Britain, although it is said to occur still in Russia. It is seen only in persons who consume quantities of mouldy rye : it appears not to occur in human beings as the result of excessive doses of the pharmaceutical preparations of ergot. Minor degrees of ergotism may, however, simulate Raynaud's disease or erythromelalgia. Gangrene due to ergot is dry, chronic in progress, extremely painful, and usually asymmetrical : it results in much disfigurement from loss of tissue, and has had a high mortality in many of its epidemics.

Patients who have been near to death from poisoning by *coal-gas* or by *carbon monoxide* are liable, after recovery, to various disorders of the circulation : and occasionally to phenomena like those of the severer types of spontaneous Raynaud's disease with superficial gangrene of the soft parts of the extremities.

A. J. Jex-Blake.

GANGRENE OF THE LUNG occurs when a portion of this organ undergoes necrosis and then, owing to invasion by one or more of many kinds of bacteria, putrefies. It usually occurs in senile, intemperate, diabetic, or debilitated patients. Most often it affects a circumscribed area of lung tissue only, but it may be a diffuse process involving a whole lung. It occurs as a rare complication of *pneumonia* or *bronchopneumonia* : and as a comparatively common complication of *aspiration pneumonia* due to direct infection of the lung by bacteria contained in food, mucous secretions, or foreign bodies generally (peas, beans, fish-bones, extracted teeth, etc.), that have made their way past the larynx and into the trachea or bronchi. Gangrene may also result from an extension of the infection in such chronic suppurative affections of the lungs as *chronic pulmonary tuberculosis*, *bronchiectasis*, or *fatid bronchitis*. In other instances the infecting agent reaches the lungs by the blood-stream : thus gangrene may follow *pulmonary embolism* if the emboli contain septic or putrefactive bacteria, secondary, for instance, to lateral sinus thrombosis due to middle-ear disease : or it may result from *penetrating wounds* of the lung, or from the *spread of infection* from the pleura, peritoneum, or pericardium to the tissue of the lungs.

Gangrene of the lung is characterized by great prostration, irregular fever, cough, and in most cases the expectoration of copious, fluid, frothy sputum of disgusting odour. The sputum settles into three layers on standing, and the lowermost of these contains fragments of elastic tissue. Severe hæmoptysis may result from gangrenous erosion of a blood-vessel. In a few cases the sputum lacks the indescribable but characteristic fætor,

oftenest so in diabetics or children. The physical signs of gangrene of the lungs are in no way distinctive; more or less extensive consolidation or infiltration of the affected part will be indicated early in the disease, and later, when the gangrenous tissue has softened and been expectorated, the signs of a cavity may appear.

As a rule, however, the diagnosis presents no great difficulty, being suggested by the supervention of copious and highly offensive expectoration in a patient known to be suffering from one or another of the diseases mentioned. The gangrene may, however, be simultaneous with the development of an *aspiration pneumonia*, and this condition may therefore be considered more fully. It is often set up by the entry of a foreign body into the trachea or a bronchus; it may follow stenosis of a bronchus from any cause, such as syphilis, or the pressure of an aneurysm or of a new growth; it may result from the establishment of a fistula from the œsophagus to the trachea or a bronchus as a terminal event in malignant disease of the air-passages or œsophagus; it is seen in patients with spreading infections of the mouth, pharynx, or larynx, especially epithelioma of the tongue; it occurs in the insane, or in persons with extensive laryngeal or bulbar paralysis who are constantly exposed to the danger of swallowing food directly into their air-passages; and it is observed occasionally after operations, particularly those on the mouth, pharynx, larynx, or trachea, when infective matter—e.g., mucus, sputum, a fragment of a tooth that has just been extracted—has made its way into the bronchi while the patient was under the influence of a general anæsthetic. All the causes just enumerated are dependent on exceptional circumstances or conditions that should be distinguished fairly easily; but in not a few instances gangrene of the lung has followed bathing, diving, or accidental immersion, though the patient could not call to mind that he inhaled any water; in the same way the origin of other cases of pulmonary gangrene has remained obscure until the patient has coughed up a piece of bone, a fragment of a tooth, part of an ear of corn, or some other foreign body that he had no recollection of having inhaled down his trachea.

In patients with pyæmia, gangrene of the lung due to multiple embolic pulmonary abscesses would be suggested if the patient should develop the signs of pulmonary consolidation, cough, and offensive expectoration. Similar symptoms occurring after *wounds* or *contusions of the chest* would make the same diagnosis highly probable.

Greater difficulty is experienced in deciding whether gangrene of the lung has occurred in a patient suffering from *bronchiectasis*, *fatid bronchitis*, *chronic pulmonary tuberculosis with cavity formation*, or *putrid empyema discharging through the lung*, where expectoration of highly offensive sputum was already present. Elastic fibres and shreds of pulmonary tissue may be, and often are, present in the sputa of all these conditions; but they are commonest, and present in greatest amount, in pulmonary gangrene. Again, the onset of pulmonary gangrene is often acute, and accompanied by much prostration, no doubt due to septic absorption; these facts, coupled with evidence of appropriate changes in the physical signs over the patient's lungs, should assist in arriving at the diagnosis.

Pulmonary gangrene may occur so soon before death as to be unsuspected; in a few instances the sputum is not foetid; in others, particularly in children, the gangrene may lead to no expectoration at all. In these circumstances the diagnosis is impossible, and the gangrene of the lung may be described as *latent*. A. J. Jex-Blake.

GASTRECTASIS. (See DILATATION OF THE STOMACH, p. 218.)

GIDDINESS. (See VERTIGO, p. 911.)

GIGANTISM (Macrosomia). Overgrowth of the body as a whole may be termed gigantism when the stature exceeds 6 ft. 6 in., or 2 metres; but there are giants of lesser height. The term is relative only. Thus it may be applied to children of excessive growth, and a distinction may be drawn between: (I) *Infantile* gigantism, or the relative overgrowth of childhood; and (II) *Adult* gigantism.

General overgrowth is prone to be associated with local overgrowths, the latter usually taking the form of tumours of some endocrine organ. In some forms of gigantism it is not possible to say to what extent the general excess of growth is caused by this local disturbance or is merely associated or correlated with it.

Gigantism is either: (1) Primary, essential, physiological, when the whole body is almost equally overgrown; or (2) Secondary, symptomatic, pathological, the result of

the unbalanced action of one or more of the endocrine organs which control the growth of bone.

I. INFANTILE GIGANTISM.

1. **Primary** infantile gigantism is usually first manifested at birth and continues into the adult form presently to be described.

2. **Secondary or Symptomatic** infantile gigantism is connected with or is due to overaction or tumours of (*a*) the suprarenal, (*b*) the pineal, (*c*) the gonadal, or (*d*) the pituitary organs.

a. The *suprarenal* form is usually, but not always, associated with a suprarenal neoplasm, and this may sometimes be detected by abdominal examination. The intelligence is often impaired. Sex characters are accentuated or inverted; consequently there are two types, sometimes more or less mixed. The *obese* form (Fig. 267) affects females chiefly, but sometimes occurs in males. With general overgrowth and conspicuous obesity there is, as a rule, a too early enlargement or exaggeration of the external sex organs, but not of the breasts or gonads. There is a tendency for masculine features to appear in the female, and occasionally this is exaggerated into definite pseudo-hermaphroditism. Pubic, axillary, and facial hair are sometimes observed, and a generalized though sparse crop of coarse hair is also a not uncommon characteristic. The *muscular*, or 'infant Hercules' type, is a rare form which occurs only in males. Muscular strength is excessive, sexual development and ossification are advanced.

Fig. 267. —Suprarenal gigantism. Baby of 13½ months, weighing nearly 60 lb. (1 st.). There is coarse hair over the body, especially on the upper lip and pubes. He was muscularly strong, but of backward intelligence.

b. In the *pineal* form the characters are similar to those of suprarenal gigantism with the addition of those of a cerebral tumour. The two groups of symptoms are probably correlative only, not cause and effect. The intelligence is normal.

As a rule this particular form affects males before the end of the third year.

c. Infantile gigantism of *gonadal* origin is distinguished by premature sexual and bodily development with normal backward mental development. Ossification finishes too early, the stature in the end being rather under than over the normal.

The *ovarian* (Fig. 268) is three times more frequent than the testicular. It may be associated with ovarian neoplasms. Sex precocity may be very conspicuous, but there are all degrees between full sexual development with fecundity and mere partial outward manifestations of sex. In the *testicular* form the organs of generation ripen too soon, and there is moderate overgrowth of the body, together with the strength and sturdiness of a more advanced muscular development.

d. Infantile gigantism may be suspected to be of *pituitary* origin when a fairly uniform spurt of growth begins in late childhood and carries the stature considerably beyond that common to the rest of the family. Signs of acromegaly may not appear until after puberty, when the disorder merges into the pituitary gigantism of the adult.

Fig. 268. —Infantile gigantism due to sexual precocity. Girl, age 3½ years, of the height usual at 8 and the sexual development usual at 11. Her intelligence was slightly defective.

II. ADULT GIGANTISM.

1. **Primary.**—In primary or physiological gigantism of the adolescent or adult (Fig. 269) the ordinary processes of growth are carried to extremes. Though growth and

development in general may be fairly well balanced, they are prone to be a little irregular, and giants of this type sometimes display such local anomalies as polydactylism, goitres, or naevi. It is hereditary, though there is often some loss of fertility.

2. **Secondary.** - In secondary or pathological adult gigantism there is disproportionate growth, chiefly of the limbs. It takes one of two forms, according to whether the fault lies in (*a*) the pituitary gland, or in (*b*) the testes.

a. The *pituitary* form of gigantism is distinguished by notable irregularities of growth and development, shown chiefly by increase in size of the nose, lower jaw, ends of the

FIG. 293. Primary gigantism. Captain and Mrs. Bates standing between two people of normal height. Captain Bates was 7 ft. 2½ in. high and weighed 450 lb. (32 st.). They had two children, the first weighing 18 lb. at birth, the second 23½ lb. Mrs. Bates was goitrous, but neither showed evidence of acromegaly.

limbs, and other termini of the body. This tendency is also displayed in conspicuous overgrowth of the skeleton, giving rise to an awkward, shambling, more or less ugly form of gigantism with mental and physical debility.

Of this gigantism of pituitary origin there are three chief varieties: (i) *Acromegalic gigantism*, in which the excessive growth occurs as part of the complex of symptoms of acromegaly (see p. 293) beginning before or during the onset of puberty. (ii) The main acromegalic features may be less prominent in comparison with those due to sex deficiency, constituting *acromegalic gigantism with infantilism*. Bone growth is then excessive, though ossification is often delayed and the sex organs are undeveloped. (iii) Sometimes instead of a mere negation of sex there is assumption of opposite sex characters, constituting *acromegalic gigantism with feminism, masculinism, or hermaphroditism*. It is not possible definitely to say to what extent these anomalies of the sex organs are caused by the morbid state of the pituitary body, or are only correlated with it.

b. *Gonadal* or *eunuchoid gigantism* is a disorder exclusively of males, and is due to arrest or deprivation of the endocrine secretion of the testes before the age of puberty. With moderate excess of height and absence of distinctive acromegalic features, there is genital hypoplasia, a tendency to lankness of figure, to knock-knees, relatively broad hips, and general effeminacy of form and conduct. The growth of the long bones obviously outpaces the growth of the soft structures. Occasionally these opposite sex characters are less noticeable, and the state is then one of *gigantism with infantilism*.

Hastings Gifford,

GIRDLE PAIN, or 'girdle sensation'—which is often a better description of the phenomenon—is a sense of constriction, sometimes of painful constriction, as though a tight band encircled the trunk. The band may be narrow or broad, and may be referred to any level of the thorax or abdomen. Although a common symptom of *tubercles*, it is not pathognomonic of that disease, and may occur with any morbid condition involving symmetrically the posterior spinal roots, such as *syphilitic spinal meningitis*.

Another form of girdle sensation, having a different pathological basis, is often described by patients suffering from *spastic paraplegia* due to focal disease within or outside the dorsal region of the spinal cord. In such a case the tight feeling is found to correspond with the highest level of spasticity, sometimes with the highest level of sensory loss. Thus a girdle sensation may be a symptom of *disseminated sclerosis*, of *myelitis*, or of *compression paraplegia*. In the last it may help the physician to localize the level of the disease, but it is rarely so reliable for this purpose as the information which can be obtained from a careful investigation of the distribution of motor and sensory paralysis and of the superficial reflexes, or by the very special method of X-raying the spine after injecting 1 to 2 c.c. of lipiodol into the spinal theca by occipital puncture (*Fig. 270*). Lipiodol is a heavy oily liquid containing 40 per cent of iodine.

E. Farquhar Buzzard.

Fig. 270. Skiagram after intraspinal injection of lipiodol, showing the level (A) at which the lipiodol is held up by a neurofibroma of the cord, the lipiodol trickling down on either side of the tumour itself (B). The neurofibroma was removed successfully. (*By Dr. Bertram Shanks for Mr. Percy Sargent.*)

GLAUCOMA. (See EYE, ACUTE INFLAMMATION OF, p. 285.)

GLYCOSURIA. The first essential in the diagnosis of glycosuria is to make certain whether the urine contains glucose or not. Many a patient has been labelled glycosuric when, by Fehling's test, there has been a partial reduction of the reagent; yet the Fehling's solution may not have been fresh; or the test-tube may not have been perfectly clean; or the urine may have contained some reducing substance other than glucose. It is important that all sources of fallacy in this

respect be avoided, especially perhaps in connection with life insurance examinations, in which even traces of sugar are regarded with profound distrust. Reagents need to be pure and fresh, and in cases of doubt confirmatory tests should be applied.

TESTS FOR SUGAR IN THE URINE.

There have been many different tests for glucose in the urine, but the two clinical tests generally employed are: (1) *Fehling's test*; and (2) *Benedict's test*. The details of each are as follows:

1. Fehling's Test.—This depends on the power possessed by glucose of reducing alkaline solutions of salts of copper, leading to the formation, on boiling, of a precipitate of red oxide of copper. Two solutions are prepared as follows: (i) Dissolve 36.64 grm. of copper sulphate crystals in distilled water and make up to 500 c.c.; (ii) Dissolve

125 grm. of potassic hydrate and 173 grm. of sodio-potassic tartrate (Rochelle salt) in distilled water and make up to 500 c.c. These two fluids should be kept in separate stoppered bottles. For use, take equal quantities of each (say $\frac{1}{2}$ in. deep in a test-tube), mix, and boil; the typical blue colour should persist. Add to the hot fluid a few drops of boiling urine from another test-tube and continue to boil. If glucose is present the colour changes first to greenish, then to orange, and even to a brick-red, the solution at the same time changing from clear to opaque owing to the formation and precipitation of a red suspension of cuprous oxide: when this reaction occurs quickly and obviously it is almost certain that glucose is present and in considerable amount. The chief doubts arise when the change of colour is delayed, or when only a greenish or greenish-yellow discoloration develops in the boiled mixture after it has been left to stand for a few minutes, and then confirmatory tests are essential: if sugar is absent, the fluid retains its blue colour and remains clear unless phosphates are brought down by boiling.

When Fehling's sugar test gives a dubious result, it is sometimes helpful to boil both the Fehling's solution and the urine in separate test-tubes and then pipette some of the boiling urine on to the surface of the boiling Fehling's solution in such a way that the two do not mix: in the presence of sugar a bright yellow ring appears at the junction of the two fluids.

2. Benedict's Test. This is a modification of Fehling's test, and similar in nature: but it is about ten times more delicate, so that proportionately smaller quantities of urine need to be used. The solution is made up as follows: Copper sulphate 18 grm.: sodium carbonate crystals 200 grm.: sodium citrate 200 grm.: potassium sulphocyanide 125 grm.: 5 per cent potassium ferrocyanide solution 5 c.c.: water to 1000 c.c. There are various modifications of Benedict's solution, but they are all similar in principle.

Sources of Error in the Above Tests. Error may be caused by the presence in the urine of other bodies besides glucose which have the power of reducing copper salts. The most important of these are *Lactose*, *Lævulose*, and *Pentose*. Lactosuria is fairly common in women who are pregnant, or who are suckling after the baby has been born: it is then no indication of disease, disappears in the intervals between pregnancies, needs no treatment, and is of importance solely in connection with the liability there is to mistake it for glycosuria. Lævulosuria is a rarity and its precise significance is obscure: it appears to have no necessary relationship to glycosuria and diabetes, but may be mistaken for the latter unless the polarimeter is used to verify the levorotatory character of the reducing substance present. Pentosuria is also rare, has little of the significance of glycosuria, may apparently be a familial peculiarity calling for no treatment, and the chief importance of the condition lies in the liability of its being misinterpreted as indicating diabetes mellitus when none exists. Each of these sugars form 'osazone' crystals with phenyl-hydrazine, but they do not ferment with yeast. Pentoses give a cherry-red colour when heated with hydrochloric acid and a little phloroglucin. They also react with the following solution (**Bial's Test**): Orcin, 1 grm.: 10 per cent solution of ferric chloride, 25 drops: strong hydrochloric acid, 500 c.c. On heating 5 c.c. of the urine with 10 c.c. of this solution a greenish-blue colour is produced, and finally a precipitate of this colour is formed.

Other substances which may cause error in testing with Fehling's solution are *Glycuronic Acid*, *Uric Acid*, *Hippuric Acid*, *Xanthin*, *Creatinin*, *Cholesterin*, and *Alcapton*. As a rule, however, they do not produce more than a dull greenish-yellow precipitate, instead of the golden colour given with glucose. They are none of them fermented by yeast. Glycuronic acid gives the reactions described as characteristic of pentose. Alcaptonuria is suggested by the dark colour of the urine (see URINE, ABNORMAL COLORATION *op.*, p. 902). The reduction sometimes seen on testing the urine of patients who have been taking certain drugs, such as morphine, chloroform, chloral, salol, camphor, phenazone, benzoic acid, or carbolic acid, is probably due to glycuronic acid.

If the urine to be tested for glucose by the copper-reduction method contains any large amount of albumin, this should be removed first by boiling and filtration. Strongly alkaline or ammoniacal urine should be rendered slightly acid with acetic acid, or instead of a golden-yellow or brick-red precipitate one may get merely a discoloration of the blue Fehling's solution without any cuprous oxide precipitate.

If neither Fehling's solution nor Benedict's solution gives any reaction for sugar, there is little need to proceed further, but if either gives a partial or nondescript result, so

that doubt remains as to whether sugar is really present, one or other, or both, of the two chief confirmatory tests for the presence of glucose should be applied. These are : (3) *The phenyl-hydrazine test* ; (4) *The fermentation test*.

3. The Phenyl-hydrazine Test.—Fill a test-tube about a quarter full of urine, add as much phenyl-hydrazine as will lie on the point of the large blade of a penknife, and a rather larger amount of sodic acetate. Boil some water in a beaker, place the test-tube in this and keep it boiling for half an hour. Then remove it and allow it to cool. If glucose be present, crystals of phenyl-glucosazone will form in the shape of an abundant bright yellow precipitate which is seen, under the low power of the microscope, to consist of dense sheaves of bright yellow needles (*Fig. 271*). Other sugars, such as lactose, levulose, and pentose, as well as glycuronic acid, form crystals with this test ; but these

Fig. 271.—Phenyl-glucosazone crystals as seen under the medium power of the microscope. Note their yellow colour, finer rays, and larger size than the sheaves of tyrosin crystals (*Fig. 326*, p. 416).

differ from those of phenyl-glucosazone in shape, phenyl-lactosazone, for example, being shorter and in the form rather of bundles than of sheaves (*Fig. 272*). The melting-points of the different compounds also differ : phenyl-glucosazone crystals melt at 206° F., phenyl-lactosazone at 200 F., phenyl-pentosazone at 160 F., phenyl-levulosazone at 204 F. In all cases of doubt the crystals should not only be inspected under the microscope ; their exact melting-point should be determined also, though this can seldom be done except at well equipped clinical laboratories where there are the necessary capillary tubes, water-baths, and so forth. The fact that phenyl-levulosazone crystals melt at almost the same temperature as do the corresponding dextrosazone crystals, and that levulose ferments with yeast as readily as dextrose does, renders it necessary to use the polarimeter if one is to distinguish the two ; this is very seldom done in practice, and it is fortunate that levulosuria is rare. Glycuronic acid usually gives rise to an amorphous precipitate, or scales, not to crystals. The urine to be tested should be free from albumin.

4. The Fermentation Test. Boil some urine (200 c.c.) in a beaker, and allow it to cool ; stir into it a piece of yeast the size of a cherry till it is thoroughly mixed. Alkaline

Fig. 272. Phenyl lactosazone crystals as seen under the medium power of the microscope.

urine should first be rendered acid with a few drops of acetic acid. Fill a test-tube completely with the fluid, close its end with the thumb, invert the tube, submerge its open end in the beaker of urine and yeast, release the thumb, and let the inverted test-tube full of yeasty urine stand for twenty-four hours in a warm place. If glucose is present, carbon dioxide gas will be formed and will accumulate at the top of the tube. If performed carefully this test is a certain indication of the presence of glucose. A small amount of fermentation may be produced by bacterial action on other sugars, but by boiling the urine in the first instance this error is eliminated. Lævulose may also ferment with yeast, but its presence in urine is so exceptional that it may practically be disregarded. A rough indication of the amount of sugar present may be gained by taking the specific gravity of the urine after fermentation, and comparing it with that of a specimen kept under similar conditions but without yeast. It is said that a fall of one point in the specific gravity takes place for every grain of sugar per ounce of urine : but this mode of quantitation is very inaccurate.

ESTIMATION OF THE AMOUNT OF SUGAR IN THE URINE.

Quantitative measurement of the glucose present may be made by either Fehling's solution or Benedict's fluid : Pavy's solution used to be employed, but it has been replaced nowadays by Benedict's solution.

If **Fehling's Fluid** is used, 10 c.c. of the mixed fluid (i and ii) are placed in a porcelain dish along with about 40 c.c. of distilled water, and heated to boiling over a flame. A burette is filled up to a known mark with the urine, diluted to 1·10 (10 c.c. plus 90 c.c. of distilled water), and this is allowed to run slowly, a few drops at a time, into the boiling fluid, which is stirred meanwhile with a glass rod. A precipitate of red oxide of copper forms, and the blue colour is gradually discharged. When the blue colour has disappeared completely, the quantity of diluted urine left in the burette is read off and the amount of diluted urine required to decolorize the measured quantity of Fehling's solution is thus ascertained : the amount of sugar in this is known to be 0·05 gm. Suppose that, for example, 8 c.c. of urine diluted to 1·10 have been used : then 8 c.c. of undiluted urine will contain $10 \times 0\cdot05$ gm. glucose, or 0·5 gm. Knowing this, the percentage of sugar is easily calculated to be $0\cdot5 \div 100 \times 8$, or 6·25 per cent.

The method of using **Benedict's Solution** is similar. The complete reduction of the copper is known by the decolorization of the fluid : 25 c.c. of Benedict's solution are equivalent to 0·05 gm. sugar.

The *Polarimeter* may also be used for the quantitative estimation of glucose : but as the instrument is not likely to be available in ordinary medical practice, it will not be described here.

THE DIAGNOSTIC IMPORTANCE OF GLUCOSE IN THE URINE.

If glycosuria of definite degree persists for any length of time (e.g., if sugar (dextrose) is found in the urine at frequent examinations during weeks or months) the patient is probably suffering from some form of *diabetes mellitus*. When, on the other hand, glucose is present on some occasions and not on others, though no special precautions, dietetic or other, are taken in the interval, it often becomes a difficult matter to decide whether the condition is merely one of glycosuria (not diabetes) on the one hand, or whether it is really one of diabetes mellitus still in an early stage and only of mild degree. Opinions differ very much as to whether it is possible to subdivide glycosuric cases into essentially different kinds, or whether all, or almost all, are really diabetic in some degree, from very mild and relatively unimportant at one extreme, to very severe and real and presently fatal at the other. Broadly speaking, the younger the patient the more serious the malady and the more definitely the dread label diabetes mellitus has to be given : many a patient in the second half of life has more or less persistent glycosuria and yet survives for many years, even when no particular dietetic restrictions are undertaken nor insulin injections given. The severity of the malady appears to diminish materially with age, and yet even in the elderly the end-result is so often a direct effect of the glycosuric state that one feels unable to distinguish the elderly from the juvenile form in kind, though one does in type and degree.

Broadly speaking, the younger the patient and the worse the prognosis, the greater is the degree of *acidosis* that accompanies the glycosuria : the urine should always be tested for diacetic acid and for acetone when sugar is present : the significance of ACETOSURIA is discussed on p. 3. In particularly serious cases the presence of acetone in the breath may be recognized by the peculiar sweet odour of the latter.

It is generally dangerous to assume that even small amounts of sugar in the urine are unimportant, and this is true even when the sugar is intermittent in its appearance : for when patients, owing to the slight and intermittent degree of the glycosuria at an early period of observation, have been regarded as not suffering from the early stages of true diabetes mellitus, it is surprising how often, a few years later, the degree of the glycosuria is found to have increased so that the condition has become one of undoubted diabetes after being one of seemingly unimportant intermittent or transient glycosuria. It is probably safer to regard all glycosurias as potential diabetes, though it may not be necessary to give a bad prognosis if care is taken with diet and general mode of life. The younger the patient the greater the care needed. It is noteworthy that there is a type of unduly heavy, almost obese, young persons whose weight in early life seems to be associated with some peculiar abnormality of metabolism in such a way that, though non-glycosuric for years, there is liability for true diabetes mellitus to develop later : and this is amongst the reasons why insurance companies dislike accepting very heavy young persons as average lives.

There are, however, certain conditions which seem prone to produce transient or temporary glycosuria which is not essentially related to true diabetes mellitus, and amongst these one may enumerate the following :—

CAUSES OF TEMPORARY GLYCOSURIA OTHER THAN DIABETIC.

Severe physical exertion : e.g., mountaineering, boat-race rowing	on the skull, cerebral tumour, meningitis	Pregnancy
Severe nervous fatigue	Fractured spine	Lactation
Cerebral injury : Concussion, meningeal hemorrhage, fractured skull, cerebral hemorrhage, cerebral thrombosis, cerebral embolism, operation	Acute alcoholism	Severe malaria
	Graves' disease	Phloridzin
	Acromegaly	Other drugs (e.g., morphine, heroin, and perhaps other opiates and anaesthetics).
	Excessive eating of carbo- hydrate : alimentary glycos- uria	

Before deciding that a glycosuria is but temporary and unimportant, it is wise to make sure : (1) that the patient's blood-sugar figure is not above the normal when, after an interval, the urine becomes spontaneously sugar-free (see below for blood-sugar estimations) ; and (2) that the urine remains permanently sugar-free after the event which is the presumed cause of the apparently temporary glycosuria has passed by. One may, never, discuss each of the items in the above list in turn before passing on to a discussion of blood-sugars, renal glycosuria, and true diabetes mellitus.

Severe Physical Exertion. The effects of severe physical exertion upon the urine have been studied particularly in rowing men. It has been found repeatedly that a healthy, well-trained man may pass a normal urine immediately before a boat-race, and yet the urine he passes soon after the race may contain both albumin and sugar. The paradox that arises from this is that the individual might be passed as a first-class life at, say, 3 p.m., and yet at 3.30 p.m. he might be turned down as uninsurable because of albuminuria and glycosuria. This effect of excessive physical strain upon metabolism, and consequently upon the urine, is but little understood, but it has an important bearing upon the interpretation of clinical phenomena : for if excessive physical exertion may cause glycosuria in well-trained athletes, minor degrees of physical exertion, fatigue, or exhaustion probably have a bearing on the explanation of some types of both albuminuria and glycosuria met with in practice. Rowing men do not tend to die of diabetes mellitus : the glycosuria which follows the extreme exertion of a boat-race seems to be transient and unimportant : the same may be caused by the effects of mountaineering, boxing, long marching, and other similar physical strains.

Severe Nervous Fatigue may be responsible sometimes for a transient glycosuria which need not pass on into diabetes. Perhaps, if the cause of the nervous exhaustion were to continue, the result might be otherwise : this we do not know for certain, but it is

important not to label a nerve-exhausted individual whose urine contains sugar for the time being an incipient diabetic until steps have been taken to watch the condition of both the urine and the blood-sugar after the mode of life has been altered so that nervous exhaustion by reason of overwork, over-excitement, late nights, short sleep, worry, or anxiety has been recovered from and is not repeated.

Cerebral Injury of any kind can produce glycosuria, just as experimental puncture of the medulla oblongata (*Stich-punkt*) does. Probably a fracture-dislocation of the spine, or a lesser injury such as comes under the heading of 'railway-spine' from a concussion accident, or from sheer fright or funk, comes under the same heading. All have as their common basis damage to the central nervous system, and glycosuria other than diabetic may result from any of the varieties given above. The details of the differential diagnosis depend upon other features of the case: but one important point arises if, for instance, a patient is found unconscious in the street, and glycosuria is found in the urine drawn off later by catheter: it does not follow that the sugar indicates a diabetic coma, for the real lesion may be concussion, a cerebral hemorrhage, or a fractured base, the glycosuria being but a transient concomitant.

Acute Alcoholism, brought to the degree of delirium or coma a 'blind drunk' — may produce a state of glycosuria which may lead to a mistaken diagnosis of diabetic coma: a fatal prognosis may be given, yet the patient, after sleeping off the effects of the drink, may recover completely and never present any glycosuria again. It may be next to impossible to say whether the sugar in the urine matters or not when it is discovered whilst the patient is still comatose: but the fact that it may be transient and immaterial should be borne in mind. The urine will probably be of low specific gravity (e.g., 1008), and not high (e.g., 1035 or 1040) as it is more likely to be in a true diabetic case, and the urinometer may assist one in deciding whether the case is diabetic or alcoholic. Acidosis with diacetic acid and acetone in the urine may occur in either condition.

Graves' Disease and Acromegaly. These diseases may be taken together so far as glycosuria is concerned. The diagnosis of the main condition will be obvious from the other symptoms: but in each disease glycosuria is apt to be discovered transiently or intermittently. The sugar-threshold may be reduced in each to such an extent that glucose appears in the urine whenever the least excess of carbohydrate is taken in the diet. On the other hand, quite apart from transient and unimportant glycosuria, out-and-out diabetes mellitus may develop in each of these maladies, and it may sometimes be very difficult to decide whether the patient is merely passing sugar occasionally without its having any material bearing on the prognosis, or whether, on the other hand, he or she is developing real diabetes in addition to the other associated malady. Blood-sugar estimations are then essential: and the higher the blood-sugar figure in a particular case the less easy will it be to pass the glycosuria as transient or immaterial.

Alimentary Glycosuria is an ill-defined state of affairs, in which the patient passes sugar in the urine whenever any extra quantity of sweets or carbohydrates is indulged in, but has no glycosuria when he is reasonably careful with his diet. Some such patients live an indefinite number of years and die of something else: others pass on and become true diabetics later on: and there is no easy way of being certain in any particular case whether the glycosuric tendency is going to remain permanently unimportant, or whether one is deluding oneself by calling the condition merely 'alimentary' when it is really the first evidence of impending diabetes. Opinions will always differ about these cases: but it is gratifying to the patient to be told that his glycosuria is not diabetic, but merely alimentary. He should, nevertheless, be cautious in the future even if drastic treatment is not called for at the moment. Many cases of 'alimentary' glycosuria are really incipient diabetics. Time alone will show to what extent the sugar matters. There is no differential test that applies with certainty at the moment: blood-sugar estimations should be made, however (see below), and also tests made as to the patient's sugar-threshold (see 'Renal Glycosuria' below). Many subjects of so-called 'alimentary' glycosuria are also subject to gout or to gouty manifestations: so that 'gouty glycosuria' is almost synonymous with 'alimentary glycosuria'. The patient is generally one who, in the past at any rate, has 'done himself well', and the probability is that most of these cases are really on the verge of diabetes, but have enough reserve not to go on to diabetes in its full degree if they begin to take care about their dietary, alcohol, and general mode of life.

Pregnancy and Lactation may be taken together. Many women pass lactose in their urines in relation to pregnancy, and this may be mistaken for glycosuria or diabetes if the phenyl-hydrazine and the fermentation tests are not applied to verify the precise nature of the sugar in the urine. Such lactosuria does not matter in the least: it passes off spontaneously and needs no treatment. Apart from lactosuria, however, pregnancy and lactation may bring out a latent tendency to true glycosuria (dextrosuria), and it is not wise to pass the case one way or the other without expenditure of greater care upon the precise diagnosis than is sometimes the case. If dextrose is found and verified it is unsafe to pass the Fehling's solution reduction as unimportant until the future course of the urine changes and of the blood-sugar changes has been watched. Some such cases prove temporary and unimportant: but some develop true diabetes mellitus later on, the pregnancy or the lactation being the first thing to bring out the latent flaw in the metabolism. Considerable clinical acumen may be required in coming to a decision: it is just as serious to alarm a patient who has unimportant pregnancy urine changes as it is to pass as unimportant that which, treated in time, may be prevented from becoming out-and-out diabetes mellitus.

Blood-sugar estimations during pregnancy have a different base line from that of non-pregnant individuals, and it may be necessary to wait till pregnancy and lactation are past before one comes to a final opinion as to what precautions, if any, the patient needs to take for the rest of her life.

Severe Malaria. In severe malaria glycosuria may be met with during the febrile spells, to disappear entirely when the infection is cured by quinine.

Phloridzin and Other Drugs. Phloridzin as a cause of glycosuria does not enter much into clinical discussion, for it is seldom employed in treatment: but its use in animals has served to throw much light upon the way glycosuria may be produced by substances, other than foods, given by the mouth. Phloridzin glycosuria is transient, and results from the effects of the drug itself. It is probable that other drugs may act in a similar way: but as most of the drugs which lead to the urine causing a reduction of Fehling's solution also tend to the secretion in the urine of definite amounts of glycuronic acid which may simulate glycosuria, it is difficult to say with much emphasis whether they are commonly causes of real glycosuria as well. There is, however, no doubt that a Fehling's solution reduction simulating glycosuria may be produced by various drugs, particularly opiates and anaesthetics, and it is a source of fallacy to be borne in mind. The effects are transient, however; and this source of fallacy is obviated if the circumstances are known and the urine is re-tested later on and found normal. Probably the effect of the opiates and anaesthetics acts partly via the nervous system, so that it may be comparable to glycosuric effects of lesions of the nervous system.

Chronic 'Simple' Glycosuria.—This occurs in elderly subjects, who are often obese, may show gouty tendencies. The urine is not markedly increased in amount, and does not contain acetone bodies. The amount of sugar present is reduced considerably by strict dieting. There is no wasting, and little alteration of thirst or appetite.

ESTIMATION OF THE PERCENTAGE OF SUGAR IN THE BLOOD.

We can now pass on to discuss definite diabetes mellitus, and its relation to renal glycosuria, in connection with which it may be of the greatest importance to know the results of estimation of the percentage of sugar in the blood.

There are various methods of estimating this, none of which, if real accuracy is to be attained, is applicable without the assistance of a special clinical laboratory. The three in general use are: (1) *MacLean's method*; (2) *Folin and Way's method*; (3) *Hagedorn and Jensen's method*.

It would be out of place to go into the elaborate details of each of these: those who require the information should consult a text-book of laboratory technique. The essential principle of each is to utilize a small quantity of blood obtained from a finger-prick or by venepuncture, accurately measured—about 0.2 c.c. is sufficient; to precipitate the proteins in the specimen; and then to estimate the sugar in the remainder by an elaborate process which depends in Folin and Way's method upon a colorimeter; in MacLean's method upon the amount of iodine liberated from a mixed solution of copper salts and

iodide of potassium, with starch solution and a standard solution of sodium thiosulphate as the indicator and estimator; and in Hagedorn and Jensen's method upon the amount of iodine set free from a mixed solution of potassium ferrieyanide, zinc sulphate, and potassium iodide in a similar way.

The difficulty with all three processes is that at least the earlier stages of the technique of sugar estimation have to be carried out upon quite fresh blood, so that it is not satisfactory to send the measured quantity of fresh blood by post; otherwise glycolysis takes place in transit and the figures obtained from the analysis are valueless. The patient needs to be taken to the laboratory, therefore, or else the analyst brought to the patient. This difficulty may be overcome when fresh methods are devised.

Renal Glycosuria. Ordinarily, when a healthy person has not recently had a meal abounding in carbohydrate, the blood-sugar figure is about 0.10 to 0.12 per cent; after a copious carbohydrate meal this figure may rise even in normal persons to 0.18 per cent, and this is regarded as the sugar-threshold for normal people, glycosuria developing should the blood-sugar exceed this figure. In diabetic patients the sugar-threshold is often raised, and may be even as high as 0.30 per cent; that is to say, it is possible for a diabetic patient to have a blood-sugar as excessive as 0.30 per cent without the urine giving any reduction of Fehling's solution. On the other hand, there are some individuals in whom sugar appears in the urine long before the blood-sugar figure reaches the outside normal sugar-threshold of 0.18 per cent; for instance, the urine may reduce Fehling's solution with a blood-sugar figure of perhaps only 0.14 per cent; this condition of affairs, when glycosuria occurs at what is termed a low blood-sugar-threshold, is generally regarded as essentially different from true diabetes mellitus, and is sometimes given the name of *renal glycosuria*. It is at any rate a state of affairs that seems to have much less serious consequences than ordinary diabetes has; and it is only diagnosable with certainty when blood-sugar figures are available; it cannot be diagnosed by estimations of the sugar in the urine alone.

True Diabetes Mellitus, in any stage in which sugar is being passed in demonstrable quantities in the urine, is nearly always associated with a raised blood-sugar figure, generally to a point beyond the outside normal maximum of 0.18 per cent, often to a figure that lies between 0.22 and 0.30 per cent, and sometimes in severe cases to relatively enormous figures such as 0.40, 0.50, or even 0.60 per cent. The higher the blood-sugar in a particular case the more certain can one be that the glycosuria matters materially; though the amount may subsequently be lessened very much by dietetic restrictions and by insulin injections, even to the extent of being brought down again to within the normal limits. On the other hand, it is found frequently that the blood-sugar figure of a diabetic patient may be well over 0.20 per cent without any glycosuria being demonstrable at all; so that in gauging the severity of the affection it is wiser to keep watch upon the blood-sugar estimations at intervals than it is to rely upon urine examinations alone.

THE SUGAR-TOLERANCE TEST.

When it is desired to investigate a particular glycosuric case in special detail it is sometimes necessary to apply what is known as the sugar-tolerance test. This consists of giving the patient 50 gm. of dextrose in 150 c.c. of water, when no food has been taken for some hours. The blood-sugar is estimated at the time, and again at one hour and at two and three hours afterwards; in normal individuals there is a rapid rise in the blood-sugar, reaching its maximum at about one hour, seldom reaching 0.18 per cent, and rapidly diminishing thereafter, so that at two hours the figure has returned to its original level; in diabetic subjects the rise may be to a higher level than 0.18 per cent, does not reach its maximum till even after one hour, and remains high still at two and at three hours in a way which is not compatible with normality; whilst at the same time the diabetic may pass sugar in his urine after the above dose, whereas, contrary to the general statements that are sometimes made, a normal individual does not generally present glycosuria even if the dose of dextrose given exceeds 200 gm. This test is not so necessary as are blood-sugar estimations in average cases, but there are many instances in which it may be of value in deciding the extent to which what might otherwise appear to be a minor state of glycosuria really matters.

TYPES OF TRUE DIABETES.

True diabetes mellitus may be subdivided into two types, which may be classified either as (1) acute, and (2) chronic; or alternatively as (1) diabetes in the young, and (2) diabetes in the middle-aged or elderly. The older the patient, generally speaking, the less acute the malady.

Acute Diabetes, occurring mainly in the young or youngish, is generally indicated by excessive thirst, polyuria, excessive appetite yet loss of weight, muscular weakness, nervous irritability, and inability to continue at work. Apart from the loss of weight, the glycosuria, the raised blood-sugar, and very often the acidosis, there may be no abnormal physical signs; though the knee-jerks often disappear even when there are no other signs of peripheral neuritis. The disease may arise without any apparent cause; occasionally it may be attributed to the effects of influenza, tonsillitis, measles, or other infective illness, or to nerve shock, or to some injury, particularly perhaps injury to the abdomen. The skin becomes dry and lustreless; the quality of the hair and nails may deteriorate; the tongue is often large and deep red, without fur; and the mentality may be changed. The urine is generally abundant, bright, clear, pale; often with a high specific gravity, e.g., 1040 or even more. Treatment by dietetic restrictions and by insulin injections may prolong life for a few years, but the end is generally ushered in by diabetic coma at a premature age, or the patient succumbs to intercurrent infection, especially to lobar pneumonia or to rapid pulmonary tuberculosis.

Lipæmia may occur in fatal diabetic cases, and its existence may sometimes be detected during ophthalmoscopic examination during life. The condition is not distinctive of glycosuric states, however, for it may be met with also in patients suffering from chronic tubal nephritis (*Fig. 273*): it may be entirely unsuspected unless blood happens to be drawn for some purpose such as a Wassermann test and allowed to stand.

Chronic Diabetes occurs in older subjects, at any age even up to 90. Sometimes the onset is definite, with thirst, polyuria, increased appetite, and loss of weight, as in the young; more often the malady begins insidiously, so that it may be discovered only accidentally in the course of an examination for life insurance, or in some other routine in which the urine needs to be tested; or attention is drawn to its possible existence by the occurrence of cataract, gangrene of a toe, acute vulvitis, eczema of the penis, scrotum, or thighs, or the development of boils or carbuncles. One curious symptom that has been known to be the first thing to attract attention to glycosuria is when ants or flies have been attracted to the ground upon which the patient has micturated out of doors. Frequently the patients may have complained of no symptoms at all; and even when the onset has been by thirst, polyuria, excessive appetite, and loss of weight, these symptoms may subside entirely in a few weeks or months, leaving the patient

Fig. 273. Lipæmia in a case of chronic tubal nephritis. The patient was a typical edematous case, but not acutely ill. The blood was taken for a Wassermann test, and became of the above appearance on standing; the fact of the existence of lipæmia was quite unsuspected.

free from personal complaint though the glycosuria is still present. Whereas in young persons the specific gravity of a diabetic urine is generally high or very high, this is often not the case in older subjects; the urine may appear to be of good normal colour, with a specific gravity that may not exceed 1018, and may be only 1010, yet with sugar present in it. Not a few cases of elderly diabetes are associated with arterial and renal degeneration, so that albuminuria, a high blood-pressure, and a big heart may be found as well as glycosuria. Certain types of individuals seem predisposed to it, particularly perhaps those who have had acute gout or a gouty family history, or those who have been of overweight as younger individuals. Women and men are affected indiscriminately. There is a belief that the condition is commoner than it was; this may be due to more skilful recognition—not always a blessing to the patient; but it may alternatively be really commoner

owing to the increasing stress and strain of modern life, or possibly to the greater inroads of chronic insidious microbial infections from such places as the teeth. Certain races seem more prone than others to suffer from diabetes in the latter half of life. Brahmins, Hindoos, and Jews particularly so. Sometimes the condition runs in families. As a general rule, though degeneration of parts of the pancreas is regarded as the essential factor in causing diabetes, there is no other objective evidence of pancreatic disease: whilst, on the contrary, diabetes is often not present when there is gross disease of the pancreas in the forms, for instance, of carcinoma of the head of the pancreas, chronic pancreatitis, pancreatic cyst or calculus.

Apart from cataract, sight is apt to be impaired progressively in senile diabetic cases as the result of either optic neuritis, optic atrophy, or a generalized neuroretinitis similar to the corresponding albuminuric state. Some diabetic patients exhibit more extensive changes in the nervous system: acute generalized painful peripheral neuritis with neuropathic muscular atrophy: lateral sclerosis of the cord: combined sclerosis of the cord: medullary degeneration with Cheyne-Stokes breathing, or with bulbar paralysis: mental degeneration with dementia from cerebral softening: or psychic changes constituting definite insanity—mania or melancholia with or without delusions. Trophic changes in the skin, apart from boils and carbuncles, may take the form of perforating ulcer of the foot, generally under the big toe (*Fig. 666*, p. 893), precisely like that seen in *tabes dorsalis*: shedding of the hair or nails: gangrene of the toe, foot, or leg, less often gangrene of the fingers, hand, or arm: and occasionally one sees a rare skin affection known as *xanthoma diabeticorum* (p. 889). The end may occur from diabetic coma, precisely similar to that of younger diabetics, though after a much longer course of the disease: or from cerebral hemorrhage: or from some intercurrent infection, particularly lobar pneumonia, in which case there is a decided tendency for the pneumonic lung to become putrid and gangrenous.

Bronzed Diabetics. There is one special form of diabetes, known as bronzed diabetes, in which the glycosuria is associated with increasing pigmentation of the skin, and in these cases there is nearly always cirrhosis of the liver as well as cirrhosis of the pancreas: the cause is probably alcohol. The condition is quite rare, but it is very characteristic and remarkable: at autopsy the liver in these cases gives quite as pronounced a blue-green Perl's test with the potassium ferrocyanide and hydrochloric acid reaction as it does in pernicious anemia.

Herbert French.

GOITRE. (See THYROID GLAND ENLARGEMENT, p. 876.)

GREEN VISION. Now and then one meets with a patient who complains that his colour vision is changed temporarily, so that things which should have other colours now appear abnormally green: when he looks out of the window, for instance, he gets the impression that his perfectly clean gravel paths are covered with green weeds, or that his wife's face looks coated with fine green powder. Sometimes this symptom is a purely mental delusion, but occasionally it results from the administration of *digitalis* in large doses, ceasing when the drug is omitted, recurring when it is given again. Other drugs may perhaps have a similar effect, but when the symptom is not purely psychic or the result of insanity the administration of *digitalis* is its commonest cause.

Herbert French.

GRINDING OF THE TEETH DURING SLEEP is a symptom which troubles the patient little, but may considerably disturb those who sleep with him: in itself it is, however, a symptom of little importance. It is popularly held that grinding of the teeth at night, especially in children, is an indication of the presence of intestinal worms, particularly of the *Oxyuris vermicularis*: it would be well, therefore, to have the faeces examined in all cases of the kind, both for parasites and for their ova. The popular belief of the association of intestinal parasites with the teeth-grinding habit is seldom verified clinically, however, and the habit may be very bad and persistent in children, or even adults, who are in perfect health. Very often it is rather a rattling of the upper teeth against the lower, owing to lateral movements made by the lower jaw as the patient, when half roused, turns over in bed: actual gritting of the teeth during sleep is far less common. It is possible that in its beginning there was a gumboil or other local irritation, which led to jaw-movements that persisted as habitual grinding of the teeth long after the primary cause was gone.

Herbert French.

GUMS, BLEEDING.—(See BLEEDING GUMS, p. 93.)

GUMS, RETRACTION OF.—(See RETRACTION OF THE GUMS, p. 731.)

GUMS, SPONGY.—(See BLEEDING GUMS, p. 93.)

HÆMATEMESIS is a term indicating vomiting of blood. It has to be differentiated from HÆMOPTYSIS: the distinction is based upon points discussed on p. 359.

Having arrived at the conclusion that the patient is suffering from hæmatemesis, the next point is to determine the cause.

CAUSES OF HÆMATEMESIS.

1. Swallowed Blood:—

Epistaxis	Bleeding from the mouth and throat	Malingering.
Hæmoptysis		

2. Diseases of the Œsophagus:—

Epithelioma	Mediastinal growth perforating the Œsophagus and aorta
Aortic aneurysm rupturing into the Œsophagus	Foreign body perforating the Œsophagus and aorta.
Rupture of varicose Œsophageal veins	

3. Diseases of the Stomach:—

Acute gastritis	Gastro-intestinal irritants, such as arsenic, phosphorus, antimony	Carcinoma
Chronic gastritis		Injuries
Toxic gastritis		Atheroma
Corrosive poisons, such as strong acids or alkalis	Ulcer	Abdominal aneurysm opening into the stomach.
	Gastrostaxis	
	Hæmorrhagic erosions	

4. Diseases of the Duodenum:—

Ulcer	Carcinoma	Gall-stone ulcerating into the duodenum.
-------	-----------	--

5. Portal Obstruction:—

Cirrhosis of the liver	} quite rarely.
Pylephlebitis (adhesive)	
Some cases of enlarged spleen, notably splenic anæmia	
Pressure on the portal veins	
Chronic heart and lung disease	

6. Acute Febrile Diseases:—

Malignant variola	Malaria	Cholera
Malignant scarlet fever	Yellow fever	Acute yellow atrophy
	Dengue	Fungating endocarditis.

7. Blood Diseases:—

Purpura	Leukæmia	Pernicious anæmia
Scurvy	Hodgkin's disease	Malarial cachexia
Hæmophilia	Chlorosis (?)	Splenic anæmia.

8. Miscellaneous:—

Chronic Bright's disease	Prolonged jaundice
Following abdominal operation	Syphilis.

It may be said at once that there are only four *common* causes of *profuse* hæmatemesis—namely, *gastrostaxis*, *gastric ulcer*, *duodenal ulcer*, and *cirrhosis of the liver*. The differential diagnosis between these is by no means always easy. The greater the history of alcoholism the more likely is the symptom to be due to cirrhosis of the liver: at this stage of the malady there may be neither jaundice nor ascites, but the liver may be felt enlarged and unduly firm, and the spleen may also be palpable. Hæmatemesis in a young, anæmic woman is more likely to be due to gastrostaxis than to ulcer, whereas in older patients, especially in males, gastric or duodenal ulcer is the probable diagnosis if cirrhosis can be excluded. The distinction between gastrostaxis and gastric ulcer often becomes one of opinion only unless X-ray examination affords positive evidence of ulcer, or unless operation is resorted to. The longer the preceding history of gastric symptoms, and the more definitely localized the epigastric pains, the more likely does ulcer become.

The diagnosis is often arrived at quickly enough ; but sometimes a routine discussion of all the possible causes is required, each being considered in turn :—

1. SWALLOWED BLOOD.

Epistaxis.—If there is obvious bleeding from the nose as well as hæmatemesis, the probability will be that some of the blood has trickled down the posterior nares into the pharynx and been swallowed and subsequently vomited. If epistaxis has taken place during the night, blood may have been swallowed unconsciously. In some cases in which no blood has come from the anterior nares examination may reveal blood trickling from the posterior nares, and the epistaxis may become evident if the patient blows his nose.

Hæmoptysis.—When blood comes from the air-passages some of it may flow back into the pharynx and be swallowed, especially if the hæmorrhage occurs during sleep. If the patient has a cough, or expectorates blood-stained sputum and presents signs of chronic pulmonary disease, the possibility of swallowed blood must be considered as a cause of the hæmatemesis, though difficulties may arise in forming a correct conclusion, for cirrhosis of the liver, for instance, is not infrequently complicated by phthisis, and so on.

Bleeding from the Mouth and Throat.—The gums, tongue, and fauces should be examined carefully, as blood from any of these sources may be swallowed and vomited later. Bleeding from the gums is most likely to occur when they are spongy, as in scurvy or mercurial stomatitis ; but the amount of hæmatemesis that can be due to blood swallowed from these sources can seldom be great.

Malingering.—The possibility of blood having been drunk in secret and afterwards vomited with intent to deceive must be considered in some cases when no cause can be found to account for its occurrence. Should fraud be suspected it may be detected by close observation. The red corpuscles should be examined microscopically in case the oval corpuscles of a bird may reveal their extraneous source.

2. DISEASES OF THE ŒSOPHAGUS.

Epithelioma.—Hæmorrhage is rare in the commonest form of epithelioma of the œsophagus which leads to an annular stricture, but it may occur from erosion of small blood-vessels as the result of the ulcerative form of the disease, the amount of blood which is brought up being small. When the ulceration is deeper and more extensive it may finally lead to perforation of a larger vessel, even the aorta, a condition which causes sudden, profuse, and rapidly fatal hæmorrhage. The diagnosis of this cause does not, as a rule, give rise to much difficulty ; dysphagia is the earliest symptom in nearly all the cases (see p. 240).

An Aneurysm of the Thoracic Aorta compressing the œsophagus may finally erode and open into it, with profuse and fatal hæmatemesis.

Rupture of Varicose Œsophageal Veins.—Varicose veins occur in the lower end of the œsophagus as a result of portal obstruction, especially that form which is due to cirrhosis of the liver, and the rupture of such veins is often followed by profuse hæmatemesis. It is, however, practically impossible to determine whether the blood comes from the lower end of the œsophagus or from the stomach, so that the diagnosis resolves itself into one of whether the patient has cirrhosis of the liver or not.

Mediastinal Growth perforating the Œsophagus and Aorta.—Vomiting of blood is an infrequent complication of mediastinal growth, but it may occur if the growth compresses and erodes the œsophagus. It is most likely to be mistaken for thoracic aneurysm or epithelioma of the œsophagus. The tendency of new growth to compress and invade the large veins, leading to œdema of the neck and upper extremities, cyanosis, and dilated superficial veins, is characteristic, and serves to distinguish it from aneurysm, in which severe venous obstruction is much rarer.

Foreign Body perforating the Œsophagus and Aorta.—Copious hæmorrhage, which may cause death, may be produced as a result of a foreign body, such as a pin, fishbone, or tooth-plate, perforating both the œsophagus and some large vessel, or even the aorta. A history of such a foreign body being swallowed, followed by a feeling of discomfort in the œsophagus, would suggest such a condition, which might be confirmed by the use of X rays, bougies, or the œsophagoscope.

3. DISEASES OF THE STOMACH.

Acute Gastritis.—The mucous membrane of the stomach in this disease is congested, and small hæmorrhages and erosions have been seen in such cases with the gastroscope. The hæmorrhage which occurs is slight, in the form of streaks of blood mixed with mucus in the vomit, and it hardly merits the term hæmatemesis. Acute gastritis is caused most frequently by errors in diet, irritating or decomposing foods, alcohol, corrosive or irritant poisons, or sepsis from septic teeth, stomatitis, or pyorrhœa alveolaris. The chief symptoms are : a feeling of discomfort and tenderness in the epigastrium, nausea, eructations, vomiting, constipation—or in children, diarrhœa—headache, a feeling of depression, furred tongue, foul breath, and concentrated urine. Pus corpuscles, or micro-organisms such as streptococci, pneumococci, or diphtheria bacilli, have been recovered from the gastric contents on appropriate examination in some cases : *anthrax* in its septicæmic stage is almost always associated with hæmorrhagic ulcerative gastritis and hæmatemesis.

Chronic Gastritis.—The mucous membrane of the stomach may be thickened and congested, with hæmorrhagic erosions scattered over its surface. The vomit usually consists of a good deal of mucus, and occasionally a little blood. It may follow acute gastritis, but most frequently is caused by the continual and excessive ingestion of alcohol, tea, coffee, and irritating and indigestible articles of diet. The main symptoms are : tenderness in the epigastrium aggravated by the taking of food, nausea, vomiting—especially in the early morning if due to alcohol—flatulence, foul breath, a furred tongue indented by the teeth at the edges, constipation, concentrated urine, and slight pyrexia. The word 'gastritis' is much misused, however : many forms of flatulent dyspepsia or indigestion are apt to be labelled 'gastritis' for the sake of giving the patient's symptoms a name, when there is no real inflammatory trouble in the stomach at all.

Gastritis due to Corrosive Poisons.—Strong acids or alkalis destroy the mucous membrane of the stomach besides injuring that of the mouth, throat, and œsophagus. Vomiting of blood and blood-stained mucus is associated with intense pain in the mouth, throat, and abdomen, dysphagia, pain and tenderness behind the lower end of the sternum or in the epigastrium, distention of the abdomen, collapse, and a rapid, feeble pulse. The urine may contain blood and albumin, and, if the poison is oxalic acid, crystals of oxalate of lime. If corrosive poisoning is suspected inspection of the mouth and pharynx will show signs of corrosion, and chemical examination of the vomit will furnish evidence of the nature of the poison.

Arsenic.—The mucous membrane of the stomach is red, inflamed, partly detached, and covered with blood-stained mucus. The chief symptoms are nausea, violent and incessant sickness, burning pain in the epigastrium, diarrhœa, faintness, and depression. The vomit is usually a brownish, turbid fluid, mixed with mucus and streaks of blood. Later, there may be severe diarrhœa, with rice-water stools. Arsenic may be detected in the vomit.

Phosphorus, antimony, and other irritant poisons may also cause inflammation of the mucous membrane of the stomach, and lead to slight hæmatemesis.

Fig. 271. To illustrate the co-existence in different parts of the same stomach of a carcinomatous and of a simple ulcer.

Gastric Ulcer. Hæmatemesis is the most important symptom of gastric ulcer, though it occurs in less than 50 per cent of the cases both in the acute and chronic forms of the disease, being due in the former to erosion of small vessels, and in the latter to the ulcerative process extending to and opening up larger gastric vessels, and occasionally even the pancreatic or splenic artery. The amount of blood varies within wide limits. If the quantity is small, or if it is gradually poured out into the stomach, it may remain there a sufficient time for the acid gastric juice to act on it and convert the hæmoglobin into hæmatin, which gives to the vomit a characteristic dark-brown 'coffee-grounds' appearance. In some cases the blood is not vomited, but appears in the stools as melæna (p. 481). If a medium or large vessel is eroded the bleeding may be very copious, a quart or more of blood being vomited, either liquid and arterial in colour or in large red clots. A profuse hæmorrhage causes sudden pallor, a feeling of faintness, restlessness, syncope, and a rapid, feeble pulse. It is rarely fatal unless a large vessel such as the splenic artery has been eroded. Occasionally hæmatemesis is the first intimation of the presence of a gastric ulcer, but in the majority of cases there are other symptoms and signs which have preceded it. The disease was formerly said to occur most frequently in females, especially of the servant class, between the ages of twenty and thirty, but not a few of these cases diagnosed as gastric ulcer are probably examples of gastrostaxis, or bleeding from a spongy, oozing mucosa without any definite and macroscopic ulceration. An analysis of 101 fatal cases showed 59 males and 42 females, and it is quite as common in later as in early adult life. It does occur before puberty sometimes—but

FIG. 273. Skiergram of his month in an hour (plus stomach, with protrusion of the hæmatin into the crater (marked by an arrow) of a large ulcer on the lesser curvature.

FIG. 276. Skiergram of a normal stomach in the erect posture after a bismuth meal. (Fig. Dr. C. Thorstein Hofflund.)

only very rarely. In addition to hæmatemesis, the signs most characteristic of gastric ulcer are abdominal pain, nausea, vomiting, and melæna. Pain is felt in the epigastrium, either just below the ensiform cartilage or at a point an inch or two lower than this, often quite localized, and either in the mid-line, or to the left of the mid-line; less often it is to the right of the middle line, seldom much so; it usually begins a few minutes after the ingestion of food, but in some cases is not experienced until about an hour afterwards; relieved if the patient vomits, or belches up wind. Pain may also be felt in the back, between the tenth dorsal and first lumbar spines. Its character and intensity are very variable, but it is usually severe and fairly local. Hyperæsthesia of the skin and tenderness on pressure in the epigastrium may also be present. Vomiting may come on immediately after food is taken, or may be deferred for an hour or two, being preceded usually by a good deal of pain. Melæna follows hæmatemesis; occasionally it may precede it, and rarely occurs independently. The tongue in the majority of cases is clean, red,

moist, and steady. There is more or less anemia; the points of distinction between gastric ulcer and anemic vomiting are discussed on page 48.

Simple ulcer is sometimes difficult to differentiate from cirrhosis of the liver or carcinoma of the stomach (Fig. 274). Examination of the stomach with the X rays after a bismuth

or barium meal sometimes affords positive evidence of the nature of the lesion (*Fig. 275*), especially when there is some stenosis of the pylorus; but it is possible to have an active ulcer and yet for the X-ray appearances of the stomach to be normal (*Fig. 276*).

Gastrostaxis (see p. 48).

Hæmorrhagic erosions are probably the earliest stage of gastric ulcer, though they may not develop beyond the phase of minute erosions. They may be the actual cause of gastrostaxis, and perhaps the distinctions between gastrostaxis, hæmorrhagic erosions, and multiple small gastric ulcers are differences of degree and not of kind. There are certain conditions, however, especially acute malignant fevers, purpura, infective endocarditis, septic states, yellow fever, blackwater fever, and anthrax, in which a general tendency to subcutaneous and submucous hæmorrhages leads to multiple small gastric erosions, which produce hæmatemesis without being directly related to ordinary gastric ulcer.

Carcinoma. Hæmatemesis is a less frequent and important sign of carcinoma of the stomach than of gastric ulcer, for it occurs in but a little over 20 per cent of the cases, and even then is generally slight. Bright-red blood is rarely seen in the vomit, for the slow ooze from the ulcer-

Fig. 277.—Skiagraph after a bismuth meal in a case of carcinoma of the pylorus and pyloric end of the stomach, marked by the arrow. (*Fig. Dr. C. Thurstan Holland.*)

ated surface of the growth allows the blood to remain in contact with the gastric juice and develop the 'coffee-grounds' appearance. About 60 per cent of the cases occur between the ages of forty and sixty. The chief symptoms and signs of the disease are: pain in the epigastric region, nausea, vomiting, anorexia, loss of weight and strength, pyrexia, anemia, cachexia, and the presence of an abdominal tumour. Pain is one of the earliest symptoms, but it varies considerably in degree and position. It is referred most frequently to the epigastrium, but is not as a rule so severe as in gastric ulcer. Vomiting is another

symptom, which varies in frequency and character according to the position of the growth. When the pylorus is involved (*Fig. 277*) and stenosed, the stomach dilates, but generally to a much smaller extent than it does when similar pyloric stenosis results from the healing of a simple ulcer; instead of the patient going several days between vomits and then bringing up large quantities of frothy brownish fluid, he is apt to be sick every day, and sometimes more than once a day, the amount brought up corresponding more or less with that of the last meal, though the latter may be discoloured by altered blood; the latter may be of 'coffee-grounds' type. When the growth is at the cardiac orifice (*Fig. 278*) the symptoms resemble those of epithelioma of the œsophagus, the food being swallowed but refusing to go down, so that after a few minutes some of it, or all of it, comes up again—by regurgitation rather than by true vomiting. In cases of growth which involves neither of the orifices but forms an ulcerating mass of the body of the stomach

Fig. 278. Skiagraph taken in the left oblique position of the thorax when bismuth was being swallowed in a case of carcinoma of the cardiac end of the stomach. The bismuth is seen to pass from the œsophagus into the proximal end of the stomach and there to be obstructed. Traces of bismuth have passed through the carcinomatous portion of the stomach and may be seen trickling through the distal end of the malignant stricture.

(Figs. 279, 280), there may be no vomiting, or if present it may have no special characteristics, the symptoms being mainly those of dyspepsia or gastritis; whilst with diffuse carcinoma of the stomach, 'indiarubber-bottle' stomach (Fig. 281), the latter may be so entirely replaced by fibrous growth that no musculature remains, vomiting is impossible, bleeding is absent, no tumour is felt, and the diagnosis may be arrived at unexpectedly on an X-ray examination after a bismuth meal, carried out because the patient has complained of being able to eat so little food at a time.

A chemical analysis of the gastric juice after a test meal may show deficiency of free hydrochloric acid, but the value of this test is limited: first because about three per cent of perfectly healthy adults show no free hydrochloric acid in their gastric contents, apparently as a normal idiosyncrasy; secondly, because there are a great many other conditions besides carcinoma of the stomach in which there is deficiency or absence of free HCl in the gastric contents, cachexia of any kind, cirrhosis of the liver, heart disease with failing compensation, enteric, pneumonia and other fevers, achylia gastrica, combined sclerosis of the spinal cord, pernicious anaemia, and many other conditions under which the patient is

Fig. 279. Skiagram taken in the erect posture, after a bismuth meal, in a case of malignant disease of the middle of the stomach, where it is marked by an arrow. The pyloric end was normal. The diagnosis was verified by operation. (See *Fig. 1, Hartman's Diseases*.)

ill enough for all his secretions to suffer, amongst them the gastric juice. All persons fail to show free hydrochloric acid in the gastric juice for some while, generally three-quarters of an hour at least, after a meal containing protein. The more the protein the longer it takes for the stomach to accumulate sufficient HCl, first to combine with all the molecules of protein as combined HCl, and later to permit of a surplus of uncombined or free HCl. Merely to test a vomit obtained at hazard is therefore of little use: one must know what food was taken previously, and how long before; it is on this account that test meals of known composition are employed, different types of meal being recovered through an Einhorn's or other stomach tube at the appropriate subsequent times. The usual meal is a test breakfast: further details are given on pp. 344 and 400.

A growth in the stomach may be seen with the aid of the gastroscope, but the use of this instrument has up to now proved too difficult for it to be adopted for general use.

The loss of weight and strength are usually progressive, and they are amongst the

Fig. 280. Skiagram taken after a bismuth meal, showing an hour-glass stomach produced by carcinoma of the body of the stomach.

most constant and characteristic signs of the disease, always meriting early attention in a patient of middle age who has never, until the last month or two, complained of any gastric symptoms whatever. Anæmia of the secondary chlorotic type, with a low colour-index, may be so prominent a symptom that a primary anæmia may be suspected until a careful blood examination has been made. Careful palpation of the abdomen may reveal an ill-defined 'slipping' epigastric tumour, but by the use of X rays and with the help of test meals it is to be hoped that diagnosis of carcinoma ventriculi may be made with increasing frequency before this stage is reached, and whilst surgical cure is still possible. The position and character of the tumour vary according to the part of the stomach which is involved. Pyloric growth may cause the abdomen to be distended as a result of gastric dilatation, and a movable tumour may be felt above the umbilicus, near the middle line and to the right of it. When the cardiac orifice is involved there may be no tumour to be felt, and the same applies to the small 'indiarubber-bottle' stomach of diffuse carcinoma ventriculi (*Fig. 281*). Tumours of the body of the stomach may be felt in the epigastrium, or below the left costal margin. It may be necessary to examine under a general anæsthetic

in some cases, and not infrequently laparotomy may be advisable as a diagnostic measure. If the patient is weighed carefully twice a week, and is proved to increase in weight steadily under treatment, carcinoma is improbable, provided this increase does not prove transient after a week or two.

Injuries.—Hæmatemesis may follow blows, stabs, or gunshot wounds in the epigastric region, or the passage of instruments or foreign bodies, such as a broken thermometer, into the stomach. The history and the evidence of any such occurrence would make the diagnosis sufficiently obvious.

Atheroma in association with arteriosclerosis or granular kidney and high blood-pressure may lead to hæmatemesis in very exceptional cases by causing weakness and rupture of small gastric vessels. Such a diagnosis should be made with extreme caution, however, even when other symptoms and signs of atheroma are present, for hæmatemesis as the result is exceedingly rare.

Hæmatemesis may be an early symptom of *splenic anæmia* (p. 466), and it is apt to recur in small amounts in some cases of *spluomegalic polycythæmia* (p. 651).

Abdominal Aneurysm opening into the Stomach.

Aneurysm of the abdominal aorta is uncommon. The sac may rupture into the stomach, however, and lead to a sudden, profuse, and fatal attack of hæmatemesis. The diagnosis may have been known previously by reason of there having been an epigastric tumour, with distinct expansile pulsation, and severe pain both in the abdomen and in the back over the site of the bulge, in a patient who has suffered from syphilis and has been accustomed to repeated and violent muscular exertion.

4. DISEASES OF THE DUODENUM.

Duodenal Ulcer.—Hæmatemesis is caused by the erosion of small duodenal blood-vessels in the base of the ulcer or by the ulcerative process spreading to and opening larger and deeper blood-vessels outside, some of the blood regurgitating through the pylorus into the stomach to be vomited, the rest passed down the intestines to produce mæna. The condition is commoner in men than in women. Some of the symptoms are similar to those of gastric ulcer, viz., hæmatemesis, mæna, abdominal pain and tenderness, anæmia, and vomiting. Hæmatemesis, however, is not so frequent as it is from gastric ulcer; it is generally less marked than is the mæna, and the latter may occur independently of hæmatemesis or before it. In the acute form of the disease there may be a copious intestinal hæmorrhage in an apparently healthy person, accompanied by acute pallor and

Fig. 281. Showing bismuth in a 'leather bottle' or 'indiarubber bottle' stomach, diffuse carcinoma of the stomach, taken after four tablespoonfuls of food (all the patient could have been swallowed). Food ran into the stomach and duodenum into the bowels. (*Cy. Dr. C. Thurston Holland.*)

followed by the evacuation of a mixture of black altered blood and bright arterial blood from the rectum. The more the bleeding, the greater the tendency for the blood passed to be still bright red. There may be no pain at all, but more often it is considerable; there is hardly any part of the abdomen to which it may not be referred, but generally it is deep-seated in the upper part, about an inch below the tip of the ninth right rib, more to the right of the middle line than is that of gastric ulcer, and usually its onset is two or three hours after the ingestion of food. One point about this pain that is almost pathognomonic is the way in which, coming on when the patient is beginning to get hungry, 'hunger pain' it is often relieved by taking food. Vomiting may be troublesome, though in some cases it is entirely absent; it is commonest when the ulcer is of chronic fibrosing type, interfering with the proper emptying of the stomach and leading to gastrectasis, in which cases the symptoms resemble those of pyloric stenosis, and it may only be when laparotomy is performed that the precise situation of the ulcer can be determined. In such cases the X rays will show a large gastric shadow and much bismuth may still remain in the stomach after eight hours; but in many cases of duodenal ulcer quite the reverse type of bismuth and X-ray may be found, the stomach itself being of relatively small

Fig. 282. Skiergram showing the crater of a chronic duodenal ulcer outlined by bismuth. The skiergram was taken two and a half hours after a bi-muth meal, when the stomach itself was virtually empty, but bi-muth still remained throughout the duodenum. The projection of the crater of the ulcer filled with bi-muth is indicated by the arrow. (Cf. Dr. L. Talbot Nathan.)

Fig. 283. Skiergram taken after a bi-muth meal, showing a hypertonic stomach of the oblique type which is often associated with non-stenosing duodenal ulcer. There was, in fact, a chronic duodenal ulcer in the patient from whom this skiergram of the stomach was taken. (Cf. Dr. L. Talbot Nathan.)

transverse type, peristaltic very actively, and emptying itself so rapidly that all the bismuth may have passed on after so short an interval as even two hours (Fig. 282). The transverse type of stomach, emptying with undue rapidity, is not necessarily associated with ulcer; but when it is found in conjunction with clinical symptoms suggestive of duodenal ulcer the fact affords further presumptive evidence in favour of that diagnosis (Fig. 283).

A test meal, whether fractional (p. 344) or otherwise, will sometimes assist the diagnosis; there is no character of a fractional test-meal result that can be called pathognomonic of either duodenal ulcer or of gastric ulcer, but, broadly speaking, the former tends to be associated with hyperchlorhydria, the latter with a total acidity and a free acidity which is not abnormally high. Figs. 284, 285, 286 are types of fractional test-meal curves from representative cases of duodenal ulcer, gastric ulcer, and gastric carcinoma respectively.

Carcinoma of the Duodenum is very rare, and would only be diagnosed if there were general symptoms of malignant disease together with a fixed tumour in the situation of the duodenum.

Gall-stones ulcerating through from the Gall-bladder into the Duodenum may cause hæmatemesis

and mæna. Previous attacks of pain occasioned by the gall-stone might lead to a diagnosis of gastric or duodenal ulcer; but if the pain was colicky in character, and

was associated with tenderness and enlargement of the liver, pain over the gall-bladder, and jaundice, it would point to a gall-stone. The diagnosis might be confirmed by the discovery of the stone in the faeces, or, occasionally, as a result of direct X-ray examination

(Fig. 324, p. 409); or, in the case of a very large calculus, by the occurrence of acute intestinal obstruction from its impaction in the small intestine. As a cause of hæmatemesis this condition is naturally very rare.

TYPICAL FRACTIONAL TEST MEALS

Charted each quarter of an hour after the test meal.

The shaded area shows the limits for free HCl in 80 per cent of normal people, and the average rate of emptying (2 to 2½ hours).

The plain lines show the total acidity. The broken lines show the free HCl.

Fig. 284. Case of duodenal ulcer with hyperchlorhydria. Many duodenal ulcer cases have no hyperchlorhydria; and hyperchlorhydria of this degree may exist without duodenal ulcer, though it generally produces suggestive symptoms.

Fig. 285. Case of gastric ulcer: there is nothing distinctive in the chart, but it serves to exclude gastric carcinoma.

Fig. 286. Case showing complete achlorhydria such as occurs with gastric carcinoma. Similar achlorhydria may be met with in some apparently normal people; it is characteristic of pernicious anaemia, and may be met with in other conditions of ill health, so that it is not by itself diagnostic of gastric carcinoma.

5. PORTAL OBSTRUCTION.

As a result of obstruction to the flow of the blood through the portal vein, passive congestion and hæmorrhagic erosion of the mucous membrane of the stomach, and varicose gastric and œsophageal veins, may be produced. Hæmatemesis may then arise through oozing of blood from the congested mucous membrane, or from an actual escape of blood in the case of hæmorrhagic erosion or the rupture of one of the varicose veins. The signs which are common to portal obstruction in addition to hæmatemesis are: nausea, vomiting, ascites, œdema of the legs, albuminuria, and the presence of dilated and tortuous superficial abdominal veins: the chief cause is:—

Cirrhosis of the Liver.—This disease is one of the important causes of profuse hæmatemesis, and it is often difficult to diagnose from gastric ulcer or carcinoma of the stomach. Hæmatemesis may be the earliest symptom, and the cause may remain in doubt until, years later, ascites and cholæmia supervene. There may be a history and the signs and symptoms of chronic alcoholism (p. 881). The liver may be enlarged and firm, but its surface at this stage is generally quite smooth and its edge as yet neither irregular nor beaded. The spleen may be enlarged as a result of the portal obstruction, but in adults rarely attains to such an enormous size as it does in the splenomegalic variety of cirrhosis in children and young adults.

Adhesive Pylephlebitis.—Non-suppurative thrombosis of the portal vein is rare, and difficult to diagnose. It may, however, give rise to sudden and profuse hæmatemesis. It is distinguished from other forms of portal obstruction by the relatively sudden onset of ascites, hæmatemesis, melæna, and enlargement of the spleen, and by an absence of signs and symptoms of cirrhosis of the liver and other causes of portal obstruction.

Pressure on the Portal Vein.—Hæmatemesis when due to this cause is generally associated with ascites and jaundice, the

common bile-duct being compressed as well as the portal vein on account of their close proximity to each other. (See JAUNDICE, p. 405.)

Some cases of Enlarged Spleen (see SPLEEN, ENLARGEMENT OF, p. 774). Hæmatemesis is met with in cases of enlarged spleen even when the enlargement is not associated with cirrhosis of the liver or leukaemia; it is particularly prone to occur in *splenic anaemia*, as the result, apparently, of close interrelationship between the vasa brevia and the splenic circulation; sometimes it results from actual thrombosis of the splenic vein, though the diagnosis of this is scarcely possible without laparotomy or autopsy.

6. ACUTE FEBRILE DISEASES.

Malignant Variola.—Hæmatemesis occurs in about a third of the cases of hæmorrhagic small-pox. It is associated with cutaneous, subcutaneous, and submucous hæmorrhages, hæmaturia, epistaxis, melæna, and bleeding from the gums. The sudden initial rigor, intense backache and headache, severe vomiting, epigastric pain, cutaneous hæmorrhages, and the diffuse hyperæmic rash with small punctiform hæmorrhages which appears first on the groins and lower part of the abdomen, would point to a diagnosis of hæmorrhagic or black small-pox if such a case occurred during an epidemic of the disease.

Malignant Scarlet Fever. In the hæmorrhagic form of scarlet fever hæmatemesis may occur; but hæmaturia, epistaxis, and cutaneous hæmorrhages are more frequent. The sudden and severe onset, the very high temperature, the rapid and feeble pulse, the headache and delirium, and the appearance of the characteristic rash on the second day would point to scarlet fever.

Malignant Measles, or black measles, is extremely rare in civilized countries, but it is met with amongst the natives of islands where measles has broken out for the first time; the hæmatemesis is less prominent than is the generalized purpura, and the diagnosis is indicated by the nature of the general epidemic.

In *Blackwater Fever* and in *Anthrax* hæmatemesis may occur without purpura, though there is a tendency to all kinds of hæmorrhages, of which blood-vomiting is but one. The diagnosis depends upon other features of the case.

Yellow Fever.—'Black vomit' due to the presence of altered blood is one of the most characteristic features of this disease. Hyperæmia and catarrhal swelling of the mucous membrane is the only change which is found in the stomach. It is essentially a disease of tropical and sub-tropical countries. The onset is sudden, with a chill, headache, and severe pain in the back and limbs. The face is flushed, and very soon jaundice appears. After the first day the pulse-rate drops, so that with a temperature of 103° or 104° the pulse may be only 70 or 80. Albuminuria is another early symptom, which may appear on the third day. In addition to the black vomit, there may be cutaneous petechiæ and bleeding from the gums. It may be difficult to distinguish from malignant malaria, unless a blood-examination reveals malarial parasites.

Cholera may be associated with hæmatemesis sometimes. The sudden onset of acute gastro-intestinal symptoms, the rapidly repeated rice-water stools, and the epidemic nature of the malady, all point to the diagnosis, which may be confirmed by recovering the vibrio from the motions bacteriologically.

Acute Yellow Atrophy of the Liver. Hæmatemesis is the commonest form of hæmorrhage in this rare disease. Women between twenty and thirty are affected more frequently than men, especially during and just after pregnancy. It sometimes follows fright and mental emotion. The first symptoms are indistinguishable from catarrhal jaundice—viz., malaise, loss of appetite, nausea, vomiting, and jaundice. The vomiting soon becomes intractable, the jaundice increases, and drowsiness, restlessness, and delirium supervene. The vomit is black, and may resemble treacle, its appearance being due to altered blood. Melæna, epistaxis, and subcutaneous petechiæ may be noticed. The tongue becomes dry and brown; the liver dullness diminishes; the urine shows characteristic changes in the marked diminution in the amount of urea and the presence of bile pigment, whilst leucin and tyrosin crystals in it (*Fig. 326*, p. 416) are an important diagnostic sign of this disease. It is not improbable that acute yellow atrophy of the liver has variable causes; and that whilst in some it is due to acute microbial toxæmia, in others it is caused by chemical substances, notably aeroplane dope varnish and trinitrotoluol; when due to the latter the patient's occupation gives a clue to the cause.

7. BLOOD DISEASES.

Purpura Hamorrhagica. Hæmatemesis may occur either as a result of blood derived from the mucous membrane of the nose or mouth being swallowed, or by reason of superficial erosions of the gastric mucosa itself. There will generally be other hæmorrhages from mucous membranes too—epistaxis, oral bleeding, hæmaturia, uterine or vaginal hæmorrhage, blood per rectum. As purpura is a symptom rather than a disease in the majority of cases, before making a diagnosis of purpura hæmorrhagica or idiopathica those diseases which lead to symptomatic purpura must be excluded—leukæmia, for instance, or pernicious anæmia (see PURPURA, p. 675). Blood-examination and general bacteriological cultures will be required.

Scurvy. Hæmatemesis occurs in severe and well-marked cases: the diagnosis depends mainly on the circumstances. The swollen spongy gums, anæmia, cutaneous hæmorrhages around the hair saes, and subcutaneous indurations, in a patient who has been living on a diet deficient in quantity and in fresh vegetables, would point to scurvy.

Hæmophilia. Out of 334 cases analysed by Grandidier, there were only 15 examples of hæmorrhage from the stomach. Excessive bleeding from slight cuts or after tooth extraction, epistaxis, bleeding from the mouth, and hæmorrhage into the joints are the earliest and the commonest manifestations of the disease. The association of hæmatemesis with hæmorrhage from other parts, and with hæmorrhage into joints in particular, in a patient whose near male relations show a tendency to bleed on the slightest provocation, would point to hæmophilia. No pathognomonic changes are to be found in the blood.

Leukæmia.—Hæmorrhages from and into various parts, especially epistaxis, are common in this disease. Hæmatemesis may be the actual cause of death. Its association with enormous enlargement of the spleen is by no means pathognomonic of leukæmia, for the two conditions may be present in chronic malaria, splenic anæmia, and splenomegalic cirrhosis. An accurate diagnosis cannot be made until the blood has been examined and a high degree of leucocytosis found (100,000 to 1,000,000 white cells per c.mm.), with a large proportion of myelocytes in the case of splenomedullary leukæmia and a high percentage of lymphocytes (90 per cent) in lymphatic leukæmia.

Hodgkin's Disease. In the late stages of this disease there is a tendency to hæmorrhage from and into various parts of the body, e.g., epistaxis, bleeding from the mouth, cerebral hæmorrhage, and rarely hæmatemesis. There should be little difficulty in making a diagnosis, as hæmatemesis would be a late symptom: the characters of the disease are described on pages 49 and 782.

Chlorosis. It is difficult to determine whether hæmatemesis occurring in an anæmic woman under thirty is due to gastric ulcer or to gastrostaxis (p. 48). That chlorosis has nothing to do with hæmatemesis, apart from the formation of macroscopic ulcers, is probable; it is also probable that chlorosis predisposes to gastric ulcer. The precise significance of hæmatemesis in a chlorotic girl may be very difficult to determine, some observers diagnosing gastric ulcer where others prefer to label the condition gastrostaxis. The former withhold solid food longer than the latter, and are perhaps inclined to recommend operation more readily; these are the main grounds for striving to draw a clear distinction between the two conditions.

Young women suffering from chlorosis are usually well nourished. The skin should have a greenish-yellow tinge to be typical. Oedema of the feet, dyspnoea, palpitation, vomiting, and amenorrhœa are prominent symptoms. The blood is pale and thin; the red blood-corpuscles are reduced in number, but are rarely under 3,000,000 per c.mm.; the average size of the red blood-corpuscles is slightly below normal; the hæmoglobin is reduced much more in proportion than are the red blood-corpuscles, so that the colour-index is low, often about 0·5 or under; the white blood-corpuscles are not increased, and the differential leucocyte-count is almost normal. Seeing that amenorrhœa and hæmatemesis are both liable to occur in anæmic girls, the gastric hæmorrhage has sometimes been regarded as vicarious menstruation; there is little evidence to support this view of its pathology, however, and when the bleedings recur the attacks seldom show any monthly regularity. Chlorosis used to be common; it is now rare.

Pernicious Anæmia.—Hæmatemesis is rare in pernicious anæmia; when it occurs

the difficulty in distinguishing between this disease and carcinoma of the stomach is much increased, especially when practically all cases of pernicious anæmia show complete absence of free hydrochloric acid from the gastric juice after a test meal. The temperature chart (p. 707) may sometimes serve to distinguish the two, for it seldom happens that a pernicious anæmia case in its severe phases exhibits no pyrexia, whereas many cases of carcinoma of the stomach have hypothermia: though on the other hand they may be pyrexial if there are secondary deposits in the liver. The absence of any pyrexia is against active pernicious anæmia, however, even if the converse is not true. A correct diagnosis cannot be made until the blood has been examined (p. 30). The urine contains pathological urobilin.

Malarial Cachexia. Anæmia and enlargement of the spleen may follow repeated attacks of malaria, and severe hæmatemesis may be a symptom. In making the diagnosis the history of residence abroad, of attacks of ague, and the condition of the blood, must be relied on. A normal or a diminished number of leucocytes, with a relative increase in the large mononuclear cells beyond 15 per cent, is strong presumptive evidence of malarial infection.

Splenic anæmia may run its course without any hæmatemesis: on the other hand, the latter is sometimes one of the most serious symptoms in the case, and may be the cause of death. The chief features of the malady are described on p. 49.

8. MISCELLANEOUS.

Chronic Interstitial Nephritis. Hæmatemesis occasionally, but very rarely, occurs in this disease. Its association with anæmia, high blood-pressure, hypertrophy of the heart, albuminuric retinitis, polyuria, and urine of low specific gravity containing a variable quantity of albumin and renal tube-casts, would point to chronic interstitial nephritis as the cause. It is most important that the blood-pressure should be measured instrumentally, and not guessed at by palpation.

Following Abdominal Operations. Hæmatemesis may occur after severe abdominal operations, independently of any injury to the stomach or duodenum. Should death occur no obvious lesion can be found in the stomach to account for it in the majority of cases. The reason for the occurrence of such an alarming symptom remains a mystery in many cases, but in some infective conditions, such as appendicitis, multiple minute erosions of the mucosa have been found.

Prolonged Jaundice. The importance of this condition as a cause of almost any variety of bleeding by oozing lies chiefly in the added danger attending operations in such cases.

Syphilis of the Liver is sometimes cited as being itself a cause of hæmatemesis: the difficulty is to exclude the possibility of alcoholic cirrhosis in such a case: it is doubtful whether syphilis alone can cause the vomiting of blood.

Herbert French.

HÆMATIDROSIS. (See SWEATING, ABNORMALITIES OF, p. 803.)

HÆMATOPORPHYRINURIA. (See URINE, ABNORMAL COLORATION OF, p. 902.)

HÆMATURIA. Blood may appear in the urine as the result of injury, of disease in some portion of the urinary tract, or of other organs involving the urinary apparatus, or of a few general diseases of other parts of the body. The blood may be present in large, small, or microscopic amounts, it may continue for days or even weeks, or, appearing suddenly and without apparent cause, may disappear completely for a variable period. Further, it may be present in the urine either as corpuscles or as hæmoglobin, and it is necessary to distinguish between the two conditions. In hæmoglobinuria the urine is dark brown from the presence of methæmoglobin, and any deposit is found to consist of brownish debris in which no red blood-corpuscles can be found (see HÆMOGLOBINURIA, p. 357). Occasionally the colouring matter of the blood may escape from the corpuscles if the stained urine has been retained for any length of time in the bladder, when crenated or disintegrated corpuscles will be found on microscopic examination of the sediment. The following list gives the chief causes of hæmaturia:—

I.—HÆMATURIA FROM AFFECTION OF SOME PART OF THE URINARY TRACT.

A. Renal Causes.

Profuse.

Malignant tumours of the kidney :
 Hypernephroma
 Embryoma
 Carcinoma
 Sarcoma
 Innocent tumours—papilloma of pelvis,
 angioma
 Injury of the kidney
 Calculus
 Tuberculosis
 So-called 'essential' hæmaturia

Slight.

Calculus
 Tuberculosis
 Renal mobility
 Hydronephrosis
 Polycystic disease
 Injury
 Oxaluria
 Nephritis, acute and subacute
 Bacilluria, and bacteriuria
 Drugs : turpentine, carbolic acid, cantharides
 urotropine, hexamine.

B. Ureteric Causes.

Calculus in the ureter.

C. Vesical Causes.

Profuse.

Villous tumour
 Papilloma
 Villous-covered carcinoma
 Prostatic adenoma or carcinoma

Slight.

Epithelioma
 Tuberculosis of bladder or prostate
 Calculus
 Acute cystitis
 Bilharzia hæmatobia
 Injury.

D. Urethral Causes.

Acute urethritis, impaction of calculus,
 injury
 Acute spermato-cystitis

Papilloma
 Nevus.

II.—HÆMATURIA FROM DISEASE OF THE NEIGHBOURING VISCERA INVOLVING THE URINARY ORGANS.

Carcinoma of the uterus, vagina, or
 rectum
 Acute appendicitis
 Acute salpingitis

Pelvic abscess
 Dysenteric or tuberculous ulceration of the
 intestine
 Diverticulitis.

III.—HÆMATURIA IN GENERAL DISEASES.

Renal infarction in endocarditis
 Arteriosclerosis
 Leukæmia
 Purpura

Scurvy
 Hæmophilia
 Acute fevers, malaria, small-pox, and yellow
 fever.

In considering the diagnosis of a case presenting hæmaturia as a symptom it is seldom that there are not other symptoms present, such as pain, tumour, or increased frequency of micturition, which will point to one or other organ as the source of the bleeding : but in some cases hæmaturia may be the only symptom. The following points will often help in the differential diagnosis :—

The Colour of the Urine.—If the urine is bright red the hæmorrhage is most likely to arise from the bladder or lower urinary tract. Dark-coloured blood in the urine may, however, be due to the retention of blood in the bladder for some time, or from the large amount present in the urine.

The Distribution of the Blood in the Urine during Micturition. If the urine during micturition is only tinged with blood during the final expulsive efforts, or the terminal urine is stained more deeply than the rest, the source of the hæmaturia is almost certainly in the bladder. If the first urine passed is blood-stained and the remainder clear, the bleeding is probably from the urethra or prostate ; whereas if the urine is evenly stained with blood throughout it suggests that the source of hæmorrhage is in the kidneys, although a vesical lesion which causes more than a slight hæmorrhage may also give rise to a deeply blood-stained urine throughout micturition.

The Quantity of Blood Present in the Urine. A large quantity of blood in the urine, in the absence of traumatism, suggests some form of growth in the bladder or kidney. Papillomata and villous-covered carcinomata in the bladder may cause sudden profuse hæmorrhage without pain or other symptom, whilst equally profuse hæmorrhage may arise from a malignant tumour in the kidney which has invaded the renal pelvis. Enlargement of the prostate often causes fairly profuse hæmaturia. Examination of any clots of blood passed may occasionally afford useful information in determining the seat of hæmorrhage. The urine should be poured into a large flat tray containing water, and the clots floated out, when some may show the triangular or pyramidal shape indicating their formation in the renal pelvis, or others the thin, worm-like form with tapering or decolorized ends from their formation in the ureter; their passage down the ureter is accompanied by the same acute renal colic that is caused by renal calculus. Clots formed in the bladder are flat, disc-like, but often broken up in their passage through the urethra.

If the quantity of blood is increased by movement or exercise, suspicion of renal stone or growth will arise. In a recent case, profuse hæmaturia occurred after three successive railway journeys, when the lesion found at operation was an early carcinoma of one kidney which had recently invaded the renal pelvis.

The Association of other Elements from the Urinary Organs with Blood in the Urine. - Microscopical examination of the deposit obtained by centrifuging the urine may reveal cellular elements distinctive of the renal pelvis or vesical mucous membrane, or epithelial, granular, and blood casts from the renal tubules (*Figs.* 9-16, pp. 6, 7), which may help in the diagnosis in a case of hæmaturia. The presence of a number of urinary crystals in a urine of acid reaction will point to renal calculus. Occasionally, small pieces of growth may be passed in the urine from the delicate villous papilloma or villous-covered carcinoma of the bladder, and more rarely plugs of muco-pus from a caseous tuberculous cavity in the kidney may be found. The presence of a villous tuft in the urine gives no indication whether it is derived from an innocent papilloma or a villous-covered carcinoma, as it becomes detached only from the surface of the growth.

The association of pus with blood in the urine does not give much assistance in determining the seat of the bleeding. Both pus and blood will often be present with either calculus or tuberculosis of the kidney or bladder, and they may both be present with vesical growth, prostatic enlargement, or coli bacilluria.

The Amount of Albumin. If the amount of albumin in the urine is in excess of that which would be due to the amount of blood present, the bleeding is probably renal in origin.

The Reaction of the Urine is of very slight assistance in determining the source of bleeding. Generally speaking, blood in an acid urine is more likely to be derived from the kidney than from the bladder; this, however, is no universal rule, for blood may be present in an acid urine in a case of vesical calculus or growth; whereas, on the other hand, there may be blood in alkaline urine in a case of renal calculus as well as in pathological conditions of the bladder.

The association of *unilateral lumbar pain*, situated in the angle between the last rib and the border of the erector spine muscle, passing forwards above the iliac crest into the groin, with occasional attacks of colic, would suggest a renal lesion; whilst hæmaturia accompanied by *increased frequency of micturition*, or by *penile pain* immediately following micturition, would indicate vesical disease; *sacral pain* with hæmaturia suggests disease in the prostate. This statement must of necessity be taken in a very general sense, for exceptions to it are frequent. Thus a vesical tumour causing hæmaturia may implicate an ureteric orifice sufficiently to cause increased intra-renal tension on that side with lumbar aching or even enlargement of the kidney; whilst on the other hand a tuberculous lesion in the kidney, with descending ureteritis, may cause increased frequency of micturition before there is any vesical infection. Equally important is it to take into consideration the *age of the patient*; thus, in a young adult, continued slight hæmaturia with increased frequency of micturition are highly suggestive of tuberculous disease of the kidney, whereas slight hæmaturia in a more elderly patient suggests vesical carcinoma or calculus. At any age, severe hæmaturia may be present with a villous tumour of the bladder, or in a patient more advanced in years with renal growth or prostatic enlargement.

Further evidence of the source of the hæmorrhage may be obtained upon the *physical*

examination of the patient. This should be carried out systematically, and not only should the urinary organs be examined, but any evidence of disease elsewhere in the body, as in the heart, lungs, blood, liver, or pelvic organs, sought for also. Each kidney should be examined bimanually, one hand being placed in the angle made by the last rib and the margin of the erector spinæ muscle, and the other in front, immediately below the costal margin: the patient is then directed to breathe deeply whilst pressure is maintained by the two hands, when an enlarged or unduly mobile kidney may be felt to descend, or may be grasped on deep inspiration. Any pain or undue tenderness on either side should be noted, especially any sharp, pricking pain experienced by the patient if the anterior hand be depressed suddenly, a sign said to be indicative of renal stone.

Examination of the bladder by palpation in the suprapubic area may elicit pain in acute inflammatory conditions, or may give evidence of a distended bladder in a case of hæmaturia from prostatic obstruction: but much more knowledge may be gained by a thorough *rectal examination*. For this purpose the patient should assume the knee-elbow position, when the examining finger can explore not only the prostate, but the vesicula-seminales, the lower end of each ureter, and the bladder base, as well as the lateral pelvic wall. The prostate may show adenomatous enlargement, or may be infiltrated with primary carcinoma—far from uncommon—when the gland presents marked, firm, rounded nodules, and is often immovable. Search should be made for any nodules in the prostate or vesicles, or thickening of the lower end of the ureter, suggestive of tuberculous disease, or thickening or infiltration in the bladder base, which may often be felt in a case of vesical carcinoma. Examination in the lateral pelvic space may show infiltration of the pelvic lymphatics or enlargement of the lymphatic glands in a case of carcinoma of the bladder or prostate. *Examination of the testes* should always be made. A nodule in either epididymis may indicate tuberculous disease which may have spread to the urinary organs, but care must be taken not to mistake a nodule dating from a gonorrhœal epididymitis for one due to tuberculous disease. Vaginal examination similarly may show thickening in the vesical base or in the lateral lymphatic areas with carcinoma of the bladder, or may give evidence of disease in the pelvic organs. The lower end of each ureter can be palpated in the fornices.

Great assistance may be obtained by the use of the *cystoscope* (*Figs. 288-293, p. 354; Figs. 571-574, p. 717*). Great gentleness must be used in carrying out any instrumentation to avoid any further hæmorrhage which would obscure a view by the cystoscope, and if any bleeding is present an attempt should be made to arrest it by irrigation of the bladder with silver nitrate 1-1000, or with adrenalin solution of the same strength. If the bleeding is profuse it may be impossible to obtain a satisfactory view of the interior of the bladder, but with even moderate hæmorrhage going on a rapid distention of the bladder may produce a medium clear enough to obtain a view which will show the seat of hæmorrhage. Thus in renal hæmaturia blood-stained urine may be seen to be emitted from one ureteric orifice (*Fig. 293, p. 354*) and clear urine from the other before the medium is too obscured; or with vesical hæmorrhage a vesical tumour may be seen. Even slight hæmorrhage will, however, rapidly render the medium in the bladder too hazy for a satisfactory examination of any minute changes in the vesical wall to be obtained—tuberculous disease, for example. In cases in which the bladder is found to be healthy, changes in the appearance of the ureteric orifice of one side, œdema, ulceration, or ecchymosis may indicate the side of the bleeding. Blood in small quantity in the efflux from a ureteric orifice may be difficult to detect: in these cases a ureteric catheter may be passed into each ureter and the urine from each kidney compared, though it must be remembered that hæmorrhage may be caused by the passage of the catheter.

I. HÆMATURIA FROM AFFECTION OF SOME PART OF THE URINARY TRACT.

A. Renal Causes.

The *Malignant Tumours of the Kidney*, hypernephroma, embryoma, carcinoma, and sarcoma, are all associated with profuse hæmaturia at intervals. Hypernephromata are the most common; they arise in the cortical portions of the kidney, and are of comparatively slow growth. The embryomata may occur in small children or in elderly persons, whilst the true carcinomata and sarcomata are much more uncommon. These tumours

cause an aching in the loin, and may lead to considerable enlargement of the kidney before any hæmaturia occurs. In the progressive growth of the tumour the renal pelvis is involved gradually and hæmaturia is evoked. This is usually severe, so that clots may be formed in the calices of the renal pelvis or in the ureter, and cause the typical pain of renal colic in their descent of the latter. The renal tumour usually maintains the shape of the kidney, but in some cases may present a nodular form. Hence profuse hæmaturia, with clots of pyramidal or worm-like shape, associated with renal enlargement, is strongly suggestive of a renal malignant growth.

The only common form of *Innocent Tumour of the Kidney* is *papilloma* of the renal pelvis. This gives rise to profuse hæmaturia and to renal enlargement which in this instance is due to hydro- or hæmato-nephrosis from the obstruction to the ureter by the papillary growth or by blood-clot. Thus the renal tumour may vary in size. Papillomata of the mucous membrane of the renal pelvis are accompanied occasionally by similar growths in the ureter, and may also show a similar growth at the ureteric orifice upon inspection of the bladder.

An *angioma* of the kidney, forming a distinct tumour in the renal tissues or developing upon the apex of a renal papilla, may cause profuse hæmaturia; this is a rare condition which is generally diagnosed as something else until the kidney is operated upon or is seen post mortem.

Injuries to the Kidney may cause hæmaturia; the diagnosis is usually obvious. The history of the accident, a blow or squeeze to the lumbar region, associated with hæmaturia, would point to an injury to the kidney. There may be renal enlargement, but this must be diagnosed from an extravasation of blood in the perinephric tissues from rupture of the renal cortex. Comparatively slight injury to the loin may produce hæmaturia from a small lesion in the renal tissues, whilst in some cases there is no sign or recollection of external violence. In any case of hæmaturia following traumatism, it is essential to diagnose an injury to the kidney from injury to the *urethra* or *bladder*.

In urethral injury the canal may be merely contused, or partially or wholly ruptured; blood may be found at the urethral meatus, or may be marked in the first portion of any urine that may be passed, whilst if the urethra be entirely divided, signs of extravasation of urine, with inability to micturate, will appear.

If the bladder be injured blood may be present in any urine drawn off; or after rupture of the bladder involving the peritoneal coat fluid may be found in the abdominal cavity. The length of time between the last passage of urine and the occurrence of the accident should be ascertained, and a catheter passed; very gentle irrigation of the bladder with sterile fluid should be carried out in any suspected rupture of the viscus, to see if the amount of fluid run into the bladder is duly returned. At the same time, a thorough examination of the bony pelvis should be made for any sign of fracture, which is frequently the cause of direct injury to the bladder or urethra.

In *Renal Calculus* the bleeding is seldom profuse, is usually associated with a small amount of pus, and frequently is increased after exertion or the jolting of a journey. The subject of a renal stone will usually complain of aching pain in one loin, which will remain of this character so long as the stone remains fixed in the renal tissues, in which condition slight hæmaturia is often present. When, however, the calculus projects into or is free in the renal pelvis the urine also contains a small quantity of pus, and attacks of renal colic come on, characterized by very acute pain in the loin, passing forwards and downwards to the groin, upper part of the thigh, and testicle of the same side, and accompanied by frequent desire to pass urine. The calculus may be passed into the bladder along the ureter, may become impacted in the course of the ureter, or may remain in the renal pelvis, in which case successive attacks of renal colic may occur. The previous passage of a small calculus per urethram, following an attack of renal colic, is an important point in the history of such a patient, but in any case an examination by skiagraphy should be carried out, when a calculus may be proved present in the kidney or ureter. (See KIDNEY, ENLARGEMENT OF; DIAGNOSIS OF RADIOGRAPHIC SHADOWS, p. 440). A calculus in the kidney may attain a size too large to become engaged in the upper end of the ureter, when renal colic will be absent, or it may cause hydronephrosis, renal abscess, or pyonephrosis, of which symptoms may be present.

Renal Tuberculosis, apart from the miliary form of children, is not uncommon as a

primary disease of one kidney. The patients affected are usually young adults, who complain of a constant aching in one loin, with occasional attacks of more acute pain resembling renal colic. At the onset of the disease, when the foci are limited to the renal tissues, there is no change in the urine beyond the occasional presence of albumin; but as it advances the foci coalesce and form a softened area which opens into the renal pelvis, when there is a constant discharge of small quantities of pus and blood in the urine. The liberation of tuberculous material into the renal pelvis and ureter causes infection of the mucous lining of these passages, and is marked almost constantly by increased frequency of micturition during both day and night, even before any tuberculous infection has occurred in the bladder. These cases are often mistaken for renal calculus or for coli bacilluria, but in any case of persistent slight hematuria or pyuria a careful search should be made for tubercle bacilli in the urine. A skiagram may show a shadow produced by a tuberculous focus in the kidney (*Fig. 287*), but this generally differs from that due to a calculus in its less definite border and by variations in the density. In renal tubercu-

losis the hematuria is rarely increased by exertion on the part of the patient, as is frequently the case with calculus, and pain in the loin is less mitigated by rest in bed. In renal tuberculosis the lower end of the ureter of the affected side may often be felt to be thickened on examination per vaginam, or per rectum, whilst in the male tuberculous nodules may be felt in the prostate or vesicles, and in either sex the cystoscopic appearances of the vesical end of the tuberculous ureter may be distinctive.

In *Renal Mobility*, hematuria is certainly uncommon, but occurs occasionally. In the case of a patient with markedly increased renal mobility hematuria may follow any strenuous exertion such as hunting or dancing. Renal mobility is so common, however, that the occurrence of hematuria should in any case arouse suspicion of some other lesion of the urinary tract, and a thorough examination both of the urine, especially for tubercle bacilli, and of the bladder (by the cystoscope) and of the kidney, should be made before any attempt at fixation is undertaken. Movable kidney may be entirely painless and give rise to no symptoms whatever, or may cause lumbar aching or attacks of acute pain resembling renal colic (*Dietl's crises*). It frequently causes gastro-intestinal disturbance from the drag upon the duodenum in relation to it, and occasionally also polyuria and increased

Fig. 287.—Skiagram in a case of tuberculous kidney with pyonephrosis; the condition, due to marked deposit of calcium salts in the old tuberculous lesions, might be mistaken for a large antlered calculus. (*By Dr. C. Thurstan Holland.*)

frequency of micturition. The kidney can be felt to be movable, but care must be taken not to mistake other abdominal swellings for a kidney (see *KIDNEY, ENLARGEMENT OF*, p. 437).

Hydronephrosis occasionally gives rise to hematuria, and the combination of renal tumour and hematuria would suggest a growth in the kidney. The blood from a hydro-nephrotic kidney, however, is very rarely copious, and the other symptoms of hydronephrosis would distinguish the two, in particular intermittency with corresponding changes in the amount of the urine. Much assistance may be obtained in the examination of a suspected renal swelling by *pyelography*—that is, the radiographic appearance of the outline of the renal pelvis and calices after the injection of some radio-opaque substance such as col-largol 5 per cent or a solution of sodium bromide 25 per cent (*Figs. 369-375*, pp. 445-447).

Polycystic Disease of the kidneys is commonly accompanied by hematuria in the later stages of the disease. It occurs in early childhood or in adult life, and is most commonly bilateral, forming an enlargement of each kidney which may reach large dimensions,

although, on the other hand, a tumour may only be felt on one side. In the early stages the diagnosis is difficult: there is polyuria with a low specific gravity urine, and, later, pain, bilateral tumour, hæmaturia, and signs of renal inefficiency will be present. The renal tumour caused by polycystic disease is smooth and rounded, but differs from hydronephrosis in that fluctuation can seldom be obtained. Bilateral hydronephrosis will be diagnosed from polycystic disease by the finding of some lesion obstructing the normal urinary flow, such as stricture of the urethra, prostatic or vesical disease, or carcinoma of the pelvic organs invading the ureters.

Oxaluria (p. 523) may give rise to slight hæmaturia. The passage of large numbers of oxalate crystals in the urine occurs in some patients, especially after a diet containing rhubarb, gooseberries, tomatoes, strawberries, and spinach, and is often accompanied by dyspepsia. An examination of the urine on successive days will demonstrate the condition. The aching in one loin, and the presence of envelope crystals in the urine, may simulate renal stone, but the absence of a shadow in a skiagram will disprove the latter.

Acute Nephritis is accompanied by hæmaturia, but is usually obvious by the rapid onset of the disease, by the history of some specific fever or of a chill, and by the subcutaneous œdema of legs, back, and eyelids. The urine is scanty and of high specific gravity, and contains, in addition to blood discs, hyaline and epithelial tube-casts, many renal epithelial cells, and abundant albumin. There are some cases of acute nephritis in which no œdema occurs, and then the abundance of renal tube-casts in the urine affords the main evidence as to the diagnosis.

Essential Renal Hæmaturia is the name given to a group of cases in which definite unilateral hæmaturia is present, but in which examination of the kidney on exploration has failed to show the cause of the hæmorrhage. The bleeding is profuse, and comes on suddenly without any apparent cause: it is intermittent, and may be accompanied by lumbar aching, but there is no tenderness and enlargement of the kidney, and on cystoscopic examination it is proved to be unilateral. In the intervals of hæmaturia there may be no albuminuria. The kidney on exploration appears to be normal, but if a piece is removed for microscopic section, evidence of nephritis will usually be found. The evidence tends to show that these cases are probably due to a unilateral nephritis.

B. Ureteric Calculus may cause hæmaturia, either during the descent of the stone or when the latter becomes arrested in the duct without causing complete obstruction to the flow of urine. The diagnosis is usually easy from the history, and the character of the pain, accompanied by the increased desire to micturate; but in some cases on the right side it may be mistaken for appendicitis. The previous history of the passage of a calculus or of symptoms of renal stone will usually be elicited. A calculus may become obstructed in any part of the ureter, though most commonly in the pelvic portion. Cystoscopic examination may show swelling and ecchymosis of one ureteric orifice, or occasionally the stone may be seen partly projecting from the orifice. Radiographic examination may show a shadow in the line of the ureter, but this should always be confirmed by a stereoscopic radiograph taken with an opaque bougie passed into the ureter. Shadows very similar to calculi may be caused by calcareous glands: these are frequently multiple and show variations in density with indistinct outline, but if single and in the apparent line of the ureter, may cause trouble in diagnosis unless a stereoscopic radiogram with an opaque bougie is obtained (see KIDNEY, ENLARGEMENT OF, pp. 442, 443).

C. Vesical Causes.

The profuse hæmaturia of a *Papilloma*, *Villous Tumour*, or of a *Villous-covered Carcinoma* of the bladder frequently occurs without any other symptom, coming on suddenly without any exciting cause: it may last a variable time, and then disappear entirely, or continue as a slight hæmaturia for some days. With the carcinomatous form there may be some increased frequency of micturition in the absence of bleeding, but in either variety the clotting of blood in the bladder may cause urgent desire to micturate or even retention of urine. A rectal examination may give evidence of infiltration of the base of the bladder or of the pelvic lymphatics in the malignant form, but it is only rarely that an innocent tumour is large enough to be felt per rectum. In the intervals between hæmorrhages, a cystoscopic examination will demonstrate the

presence of a vesical growth (Figs. 288, 289). It should be noted that the common situation for a vesical tumour is at the base of the bladder, in close proximity to a ureteric orifice; the latter may be obstructed, or dragged upon by the growth in such

Figs. 288-293.—BLADDER APPEARANCES SEEN THROUGH THE CYSTOSCOPE.

manner as to cause renal distention or hydronephrosis, so that a vesical tumour may give rise to renal pain and tumour, and in this way be mistaken for a renal growth. This difficulty will be overcome by a cystoscopic examination of the bladder.

Prostatic Enlargement of the adenomatous, or more frequently of the carcinomatous variety, may cause hæmaturia. The age of the patient (54 or more), the increased frequency and difficulty in micturition, the evidence obtained by rectal examination and by catheterization, suffice to diagnose the disease. The hæmaturia of prostatic enlargement is often profuse, and may occur early in the disease: but on careful inquiry it will usually be found that there has been for some months a gradually increasing frequency of micturition.

Vesical Epithelioma occurs in elderly patients, and causes slight but fairly constant hæmaturia. For hæmorrhage to take place from a vesical epithelioma there must be ulceration of the surface of the growth, and other symptoms will be present, namely, increased frequency of micturition both day and night, penile pain following the act of micturition, and pyuria. The blood often occurs as a few drops at the termination of urination, or may be mixed throughout the act. Usually a vesical epithelioma is situated on the base of the bladder, and may be felt as a distinct infiltration per rectum.

Vesical Tuberculosis gives rise to exactly the same symptoms as an epithelioma, but it occurs commonly in young adults. Persistent slight hæmaturia and pyuria in a young patient will always suggest tuberculous disease, and a very careful search should be made in the centrifugalized urine for tubercle bacilli, whilst other evidence of tuberculous disease, especially in the testes, vesiculæ seminales, and prostate, should be looked for. Tuberculous disease of the urinary organs occurs as a primary disease, though frequently there is evidence of former tuberculous disease in the chest or other sites. Apart from an infection secondary to disease in the generative organs, tuberculosis in the urinary organs almost always commences in one kidney, in an area which softens and opens into the renal pelvis. Infection then occurs in the mucous and submucous coats of the pelvis and ureter, as well as in the peri-ureteric lymphatics, and spreads to the bladder. Even before there is any visible infection of the latter there is persistent pyuria, hæmaturia, and increased frequency of micturition, so that vesical disease may be thought to have commenced whilst the infection is limited to the kidney. Cystoscopic examination may reveal changes in the ureteric orifice of the affected side or evidence of vesical infection (*Figs. 573, 574*, p. 717). A careful rectal or vaginal examination may show an enlarged and thickened ureter. When tuberculous disease spreads to the bladder from the direct ulceration of a prostatic or vesicular focus, hæmaturia is usually present. Examination of the testes and of the prostate and vesicles will reveal the nature of the infection.

Vesical Calculus also causes slight hæmaturia, usually as a few drops in the terminal urine. The subject of a calculus in the bladder unaccompanied by cystitis will complain of increased frequency of micturition during the day or during exercise, but is usually free from micturition during the night. There is pain of a pricking character in the glans penis after micturition, and there may be a history of sudden stoppage of the stream during the act. The patients are usually men, and there may be a history of previous calculi in the bladder or of attacks of renal colic with the descent of a renal calculus which has not been passed per urethram, but which has increased in size since it entered the bladder. The stone may be felt with a sound, or, better still, seen by a cystoscope, with which small calculi which may be missed with a sound may be diagnosed with certainty (*Fig. 292*). The X rays are also useful in detecting the stone in many cases (*Fig. 294*). If the calculus has caused cystitis, there will be in addition pyuria and nocturnal micturition.

Acute Cystitis is accompanied by hæmaturia: but the other symptoms, such as vesical tenesmus, suprapubic pain, and pyrexia, together with pyuria and a cause for the condition, will point to the disease.

Bilharzia Hematobia causes slight hæmaturia, and gives rise to symptoms very similar

Fig. 294. Skigram of a composite (oxalate and phosphate) vesical calculus. C, Calculus; R, Pelvic colon; S, Symphysis pubis. (By Dr. Alfred C. Jordan.)

to vesical tuberculosis. The discovery of the typical ova in the urine (see *Fig.* 96, p. 102), together with a history of residence in an affected district, notably Egypt or certain parts of South Africa, will make the diagnosis clear. The cystoscopic appearance in the bladder of small, glistening yellow nodules and small areas of raised granulation tissue is distinctive of the disease (*Fig.* 291).

D. Urethral Causes.

Acute Urethritis, whether gonococcal or septic, may cause blood in the urine from the acute congestion of the urethral mucous membrane. The history and the presence of an acute urethral discharge make the diagnosis evident.

The *Impaction of a Calculus* in the urethra causes some bleeding from direct injury to the urethral mucous membrane. There is usually retention of urine, so that true hæmaturia may not occur; but the history of sudden stoppage of the stream of urine during micturition, with acute penile pain, together with the previous history of renal or vesical stone, will usually make the diagnosis clear. It is not uncommon in male children. The calculus may be felt from the outside in the course of the urethra, often at or near the meatus, or seen by an endoscopic examination.

Nævus of the urethral mucous membrane is a rare but important cause of severe and recurrent hæmaturia, the patient generally presenting no other symptoms beyond the spontaneous bleeding and serious anemia resulting from it. The blood is passed both with and apart from micturition. There may or may not be bleeding nævi elsewhere; but the condition is precisely analogous to the small bleeding nævi of the tongue and mouth that have been described in conjunction with nævi of the skin by Osler and others (*Figs.* 299, 300, p. 368). The diagnosis of a urethral nævus could scarcely be made with certainty except by urethroscopy.

II. HÆMATURIA FROM DISEASE OF THE NEIGHBOURING VISCERA INVOLVING THE URINARY ORGANS.

The direct spread of *carcinoma* of the pelvic organs may in its progress involve the bladder, as is not uncommon in the later stages of carcinoma of the uterus, vagina, rectum, or pelvic colon. The infiltration of the bladder wall before actual ulceration has occurred is usually indicated by vesical irritability, followed by ulceration and hæmaturia, together with the passage of urine by the vagina or fecal matter in the urine. Occurring as a late stage of carcinomatous disease there is usually little difficulty in the diagnosis.

Hæmaturia may occur during an attack of *acute appendicitis* from the direct spread of the inflammatory process to the vesical wall. In some cases in which the inflamed appendix turns downwards over the pelvic brim it may become adherent to the bladder, or an abscess may form in immediate relation to the bladder wall. The localized inflammation of the vesical mucous membrane causes hæmaturia, whilst the sudden appearance of a quantity of pus in the urine has been noticed when an appendicular abscess has ruptured into the bladder. The history of acute pain low down in the right iliac fossa, the pyrexia, and general symptoms of peritoneal inflammation before any urinary symptom was noted, will point to the disease; a rectal examination may reveal the inflammatory process in the right pelvic region.

Acute Salpingitis or *Pelvic Abscess* may similarly cause hæmaturia from direct inflammatory extension to the vesical wall, but this is rarer than in appendicitis.

Tuberculous and *Dysenteric Ulceration of the Intestine* have both caused hæmaturia by the adhesion of the bowel to the fundus of the bladder and the subsequent inflammatory condition of the mucous membrane. In a case of slight hæmaturia a cystoscopic examination showed a localized area of intense congestion at the fundus of the bladder without any other vesical lesion, and on opening the abdomen, a coil of small intestine, obviously ulcerated by tubercle, was found adherent to the peritoneal aspect of the bladder. In most cases the symptoms due to the intestinal disease would be apparent.

Diverticulitis occasionally results in a pelvic abscess which may ulcerate into the bladder, giving rise to hæmaturia, and to an intestino-vesical fistula. The preceding history of the passage of blood and mucus per rectum and of irregularity of the bowels is very similar to that of colonic carcinoma, and the diagnosis is seldom certain until laparotomy has been performed.

III. HÆMATURIA IN GENERAL DISEASES.

The sudden plugging of a renal vessel by embolism (*renal infarction*) is not uncommon in cases of endocarditis, and may be accompanied by hæmaturia. Embolism is seen most commonly in infective endocarditis: it is indicated by sudden pain in the loin, followed by hæmaturia. The occurrence of acute endocarditis in the course of acute septic processes, such as acute osteomyelitis, pneumonia, or acute rheumatism, is not uncommon, and will usually be diagnosed before there is any evidence of renal embolism. On the other hand there are certain cases of chronic heart disease in which the first evidence of infective endocarditis having become superadded may be the occurrence of sudden hæmaturia: and in some such cases there may be difficulty in excluding acute Bright's disease, because around each infarct there is local acute inflammation, and therefore the urine will contain tube-casts as well as blood: the other signs of infective endocarditis (p. 15) should be watched for.

Leukæmia may be accompanied by hæmaturia: but the enlargement of the spleen, general symptoms of anæmia, and the total and differential blood-counts (pp. 32-35) will point to the diagnosis.

Scurvy and the various forms of PURPURA (p. 675) may each be accompanied by hæmaturia, but the general symptoms of each disease are usually well marked before this occurs.

R. H. Jocelyn Sear.

HÆMOGLOBINURIA differs from hæmaturia in that the blood pigment is passed in solution in the urine apart from red corpuscles: small numbers of red corpuscles, or their ghosts, may be found microscopically, but these constitute hæmaturia in association with the hæmoglobinuria: the essential part of the latter is the passage of the blood pigment dissolved out of the red corpuscles. It gives the same chemical tests as ordinary blood: spectroscopically it is almost as common to find the bands of methæmoglobin (*Fig. 22*, p. 13) as those of oxyhæmoglobin (*Fig. 17*, p. 13): by the addition of ammonium sulphide the spectrum is changed to that of reduced hæmoglobin (*Fig. 18*, p. 13), and by the further addition of a few drops of concentrated caustic soda that of alkaline hæmatin (*Fig. 20*, p. 13) is produced. The diagnosis depends upon the discovery of blood pigment in the urine, whilst the microscope shows no red corpuscles, or so few as to be out of all proportion to the pigment. It is important that the urine should be examined fresh, for otherwise, owing to the disintegration of red cells after they have been passed as such, it is possible to mistake for hæmoglobinuria that which is really hæmaturia. To the naked eye the urine may be only just tinged with a colour that suggests blood pigment, or it may be absolutely blood-red, brown, murky, or even black, as in tropical blackwater fever. It is seldom clear; but clouded by mucus, casts, amorphous masses of pigment, and debris.

Hæmoglobinuria results from any condition which leads to hæmoglobinæmia by laking the red corpuscles within the living vessels. It has been produced in animals experimentally by the injection of various hæmolytic sera and other substances. It may occur in man as the result of the oral administration of certain chemical substances, such as potassium chlorate, phenylhydrazine, turpentine, ether, carbon bisulphide, pyrogallie acid, naphthol, carbolic, hydrochloric, sulphuric, nitric, oxalic, and chromic acids, glycerin, chloroform, sulphonal, veronal, trional, tannin, saponin, strychnine, urotropine, impure aspirin, and possibly quinine: after the inhalation of certain toxic gases, notably carbon monoxide, naphtha vapour, arseniuretted, antimoniuiretted, phosphoretted, seleniuretted, or sulphuretted hydrogen: after the transfusion of blood from a donor who is not quite of the right group for the recipient, after intravenous injection of normal horse serum, or of anti-tetanic, anti-meningococcal, anti-dysenteric, anti-diphtheritic, anti-streptococcal, anti-pneumococcal, or anti-anthrax sera, or after the introduction of such poisons as those of snakes, venomous toads, or spiders: from ricin, abrin, robin, croton, phallin: after eating poisonous mushrooms, toadstools, or truffles: after frostbite and extreme exposure to cold: after severe burns: after large internal extravasations of blood, especially those within the abdominal cavity: in a few cases in which pregnancy is associated with toxæmic symptoms: in some new-born infants, occasionally in an obscure epidemic form: in association with certain functional disorders of the vasomotor system, especially

Raynaud's disease, factitious urticaria, and angioneurotic oedema; after very long-sustained excessive physical exertions and fatigue; in association with severe forms of microbial—or presumably microbial—toxaemia, especially malaria and blackwater fever, and to a much less extent in severe syphilis, typhoid fever, acute pyogenic septicæmia, generalized anthrax, yellow fever; in Hænoch's purpura; in certain cases of nephritis; and in that remarkable affection known as paroxysmal hæmoglobinuria.

In connection with blood transfusions it is noteworthy that, if the same donor is used a second time, hæmoglobinuria may follow the second transfusion when none accompanied the first.

Although the above list may appear formidable, the differential diagnosis between the different diseases mentioned will seldom depend solely upon the presence or absence of hæmoglobinuria. The chief importance of the latter, indeed, lies first in the necessity of not mistaking it for hæmaturia, and secondly in that its occurrence is a sign that considerable hæmolysis is taking place and that the prognosis is proportionately less good.

The question of whether *blackwater fever* is due to the effects of quinine in a patient whose blood is already susceptible to hæmolysis on account of malaria, or whether the blackwater is due to a distinct and specific malady, has not yet been settled, though there is increasing evidence that 'blackwater' may be due both to a pyrexial malaria-like illness that has a different hæmatozoal cause from that of ordinary malaria, and to particularly severe infection with malaria itself; the diagnosis is suggested by the geographical circumstances under which the disease develops.

Paroxysmal hæmoglobinuria is rare; but in Great Britain it is probably the commonest cause of considerable hæmoglobinuria without symptoms of extreme illness. It may affect children, adolescents or grown-up people, males or females; it has probably several different ultimate causes; amongst the latter, however, previous syphilis stands out pre-eminently, and probably heredity is also a factor. Males are affected rather than females. The remarkable feature of the malady is the way in which an attack can be brought on, almost at will, by certain immediate causes, of which the most potent is exposure to cold, others being excessive exercise or mental excitement. Sometimes the exposure has to be considerable before hæmoglobinuria results; on the other hand, it may be impossible for the patient to keep his hands immersed in cold water for any length of time without an attack ensuing. The urine may look like blood; the output of pigment, together with considerable albuminuria, persists for a day or two, or several days; the attack may be unaccompanied by other symptoms, but sometimes there is a shivering attack or an actual rigor with rise of temperature and a general feeling of illness, necessitating rest in bed. If repeated attacks occur at short intervals, the patient becomes anæmic, with all the symptoms that result from such anæmia. The diagnosis may be difficult at the time of the first attack, but it is relatively easy when the attacks recur, especially when there

is distinct relationship to some definite immediate cause, such as exposure to cold, undue fatigue, or mental excitement. The main mistake to avoid is a diagnosis of hæmaturia, such as a villous tumour of the bladder might cause. The way to obviate this error is to employ both the microscopic and the spectroscopic tests for blood, much pigment and few corpuscles pointing to hæmoglobinuria. If there is still doubt as to whether the patient has paroxysmal hæmoglobinuria, a little of his blood serum, obtained by venepuncture, should be examined in the laboratory for Eason's reaction, a complex serum test which is positive in essential hæmoglobinuric cases, negative in others; the Wassermann reaction would probably be tested at the same time to determine whether the cause was syphilis, as it so often is.

Herbert French.

HÆMOPTYSIS literally means blood-spitting, but clinically it is restricted to expectoration of blood derived from the lungs, bronchi, or trachea, to the exclusion of blood from the mouth, nose, or pharynx. Some include blood coming from ulceration of the larynx under the heading of hæmoptysis; others do not, so that the meaning of the term is arbitrary; for practical purposes it is simpler to include the larynx as a source for hæmoptysis.

The differential diagnosis resolves itself into two main portions, namely: (I) A determination of whether the symptom has really been hæmoptysis in the restricted sense, or whether the blood has been derived from the mouth, nose, or pharynx on the one hand, or

the stomach on the other ; and (II) If true hæmoptysis has really occurred, a determination of its exact cause in the particular case.

I. THE DISTINCTION BETWEEN TRUE AND SPURIOUS HÆMOPTYSIS.

True hæmoptysis—that is to say, hæmorrhage from the lungs, bronchi, trachea, or larynx—can sometimes be distinguished at once from the spitting of blood derived from the nose, mouth, or pharynx. The occurrence of epistaxis, bleeding gums, tonsillitis, ulcerative stomatitis, epithelioma linguæ, injury to the mouth, gingivitis, dental caries, pyorrhœa alveolaris, pharyngitis, septic conditions of the antrum of Highmore or frontal, ethmoidal, or sphenoidal air-cells, or rarer conditions such as lupus of the palate or sarcoma of the tonsil or of the basisphenoid, may generally be detected by a careful examination of the nose, mouth, gums, and pharynx ; moreover the blood in these conditions is usually mixed with saliva, and watery. It is important, however, to be decidedly guarded in concluding that blood comes from the mouth, nose, or throat, and not from the lungs ; and a careful examination of sputum for tubercle bacilli, and an X-ray examination of the lungs should be carried out in every such case, lest the early stage of phthisis be missed.

The distinction between hæmoptysis and hæmatemesis is often easy, but sometimes very difficult. The history may help, or the patient's own sensations may make him certain that he coughed up blood, and did not vomit it. The following is a summary of the points of distinction :

HÆMOPTYSIS.

1. The patient *coughs* the blood up
2. Part of the blood is often frothy
3. The blood may occur by itself, but it is often mixed with sputa, recognizable microscopically
4. The blood is alkaline in reaction
5. Tubercle bacilli or elastic fibres may be detected
6. There may be a previous history of acute rheumatism, or of cough and night sweats, indicative of heart or lung disease, confirmed by abnormal cardiac or pulmonary physical signs
7. Before the blood is coughed up there is often a sense of tickling or gurgling in the throat, always suggestive of true hæmoptysis
8. The motions are not altered afterwards unless the blood has been abundant and much of it has been swallowed, when they may be tarry as in hæmatemesis
9. Blood-stained sputa may be expectorated for several days after a severe attack
10. A history of cough

HÆMATEMESIS.

1. The blood is *vomited*
2. The blood is not frothy
3. The blood may occur by itself, but it is often mixed with vomit, recognizable by the presence of food particles
4. The blood may be alkaline if it is abundant, but it may be acid from admixture with gastric juice.
5. Tubercle bacilli will be absent
6. There may be a definite history, with or without physical signs, pointing to a gastric lesion or to cirrhosis of the liver
7. Before the blood is brought up there may be a feeling of sickness, nausea, oppression in the epigastrium, faintness, and giddiness
8. The motions are often black and tarry afterwards
9. There are usually no sputa
10. A history of abdominal pains after food.

Notwithstanding all these points of distinction, however, one may be misled unless the patient can be kept under observation for a time ; moreover, hæmatemesis may be caused by hæmoptysis, especially when the bleeding takes place in the night, the blood being swallowed as soon as it gets into the pharynx whilst the patient remains asleep and quite unconscious of the occurrence. The frequency with which hæmoptysis occurs during the night when the patient is at rest is remarkable ; but in the majority of instances the incidence of bleeding excites coughing, and the patient wakes.

Malingering by the production of blood-spitting by gum-sucking is diagnosed upon circumstantial evidence. It has sometimes happened that a patient has produced the blood of fowls with the statement that this has been coughed up—a fallacy that can be detected by finding oval instead of circular red cells under the microscope.

Redness of the sputum is not always proof that the colour is due to blood ; the presence of red cells should be verified under the microscope, and the guaiacum and

ozonic ether or the benzidine test also applied; occasionally patients have been regarded as suffering from recurrent phthisical hæmoptysis when in reality the redness of the sputum has been due to infection of the respiratory passages by relatively unimportant pigment-producing micro-organisms, generally of the *Bacillus prodigiosus* type; this source of fallacy is to be avoided by having careful bacteriological examinations of the sputum made in all cases that are not perfectly straightforward.

II. DETERMINATION OF THE CAUSE OF THE HÆMOPTYSIS.

Having arrived at the conclusion that a patient has had hæmoptysis, the next point is to ascertain its cause. By far the commonest are *phthisis* and *mitral stenosis*. The heart and lungs need particular examination therefore, and the family and personal history, both as to acute rheumatism or chorea, and as to consumption, may assist. If there are no abnormal physical signs in the thorax it does not follow that phthisis is absent— even phthisis with cavitation may exist without any definite abnormal physical signs being detected; microscopical examination of the sputum, therefore, both for tubercle bacilli and for elastic fibres, should never be omitted, especially after hæmoptysis has ceased—

Fig. 295. Temperature chart, taken two hourly, in a case showing a positive reaction to tuberculin injection of Koch's old tuberculin. Note the latent period of about twelve hours preceding the rise of temperature after the injections. The diagnosis lay between chronic bronchitis and pulmonary tuberculosis, and was confirmed independently by the discovery of tubercle bacilli in the sputum.

repeated examinations may be required if the first proves negative; and the chest should be X-rayed.

When the patient is apyrexial and there is much doubt left in the mind as to whether tubercle is the cause in spite of the use of all the more ordinary methods of diagnosis, it is occasionally important to resort to the tuberculin-injection test. Notwithstanding earlier fears, this has been shown to be a perfectly safe proceeding; but if the result is positive it does not prove that the patient has phthisis pulmonalis, for there might be tuberculosis elsewhere, and not in the lung—glandular tuberculosis for example. The

Fig. 296. --Temperature chart showing a negative tuberculin inoculation reaction. The case was one of chronic bronchitis; no tubercle. Compare with Fig. 295.

test is, perhaps, of greater value when it is negative than when it is positive. That it has a real value in certain instances, however, is clear, provided that the tuberculin employed has been verified as to its activity by previous tests in other cases. The tuberculin employed is Koch's old tuberculin, in a dilution of 1:1000; half a c.c. of this is used for the first injection, and if the result is negative a second dose of 1 c.c. is given four days later; some observers give even a third dose of 2 c.c. after another interval of four days. The temperature should be recorded as nearly as possible two-hourly whilst the test is being made; a positive reaction is indicated by a rise in the chart after a characteristic latent

period of about twelve hours, the rise being as a rule more abrupt than the fall, and the whole pyrexial response being over in something between twenty-four and forty-eight hours. The actual height of the temperature rise varies much in different cases, and the height is less characteristic than is the latent period and the general look of the chart. A typical positive chart is shown in *Fig. 295*, whilst *Fig. 296* shows a negative result in a corresponding non-tuberculous case. Simultaneously with the temperature response there are positive local changes in the skin at the site of the injection: swelling and redness over a fairly wide area, almost like a local patch of erysipelas: the skin changes take a little longer to subside than does the pyrexia. The difficulty is that it is by no means easy to obtain a supply of Koch's old tuberculin of precisely the right activity: and unless it is kept in bulk and diluted when required, it is apt to deteriorate, especially if, after dilution to 1:1000, it is sealed off into glass tubes or bulbs. It does not keep well thus: but if it is possible to obtain a good stock tuberculin, tested clinically and found to give positive reactions in known positive phthisis cases with tubercle bacilli in the sputum, and negative results in people in good health, its use in the way indicated above for diagnostic purposes in apyrexial cases of dubious phthisis is often of great value.

Although phthisis or mitral stenosis are the commonest, there are a great many other causes of hæmoptysis, as the following tables indicate:

A. Hæmoptysis due to Changes in the Lungs:

- | | |
|---|--|
| 1. Phthisis: (a) Early: (b) Later | 8. Septic pneumonia, with or without abscess |
| 2. Cirrhosis of lung: pneumonococcosis: | 9. Gangrene of the lung |
| a. Knife-grinder's lung | 10. Infarction of the lung: |
| b. Stonemason's lung | (a) Embolic: (b) Thrombotic |
| c. Miner's phthisis | 11. Neoplasm of the lung, whether primary or secondary: |
| 3. Cardiac disease, especially mitral stenosis | a. Sarcoma: b. Carcinoma |
| 4. Violent coughing efforts, as in whooping-cough or bronchitis | 12. Sporotrichosis of the lung: |
| 5. Injury to the chest: | a. Aspergillosis |
| a. Blows upon the chest wall | b. Actinomycosis |
| b. Fractured rib | c. Other forms |
| c. Exploratory needling | 13. Aortic aneurysm pressing on and opening into the lung |
| d. At the end of paracentesis thoracis | 14. Empyema bursting through the lung |
| 6. Lobar pneumonia | 15. Hepatic abscess bursting through the diaphragm into the lung |
| 7. Bronchopneumonia | 16. Hydatid cyst. |

B. Hæmoptysis due to Changes in the Bronchioles, Bronchi, or Trachea:—

- | | |
|---|---|
| 1. Bronchitis: | ii. Invasion of a bronchus by a mediastinal sarcoma, lympho-sarcoma, oesophageal epithelioma, or other neoplasm |
| (a) Acute: (b) Chronic: (c) Plastic | c. Secondary to a foreign body, such as a button, a fruit-stone, a tooth, etc.: or to a tracheotomy tube |
| 2. Bronchorrhœa | d. Secondary to a caseous or calcareous bronchial gland |
| 3. Bronchiectasis | 6. The effects of irritant gases, notably: |
| 4. Aortic aneurysm opening into the trachea or a bronchus | Chlorine |
| 5. Ulceration of the trachea or a bronchus: | b. Mustard gas |
| a. Tertiary syphilitic | 7. Parasitic infection by <i>Distoma pulmonale westermanni</i> . |
| b. Malignant | |
| i. Primary epithelioma of bronchus | |

C. Hæmoptysis due to Changes in the Larynx:

- | | |
|---------------------------------|---|
| 1. Acute laryngitis | 7. Injury to the larynx, by a blow, a throat grip, a cut throat, intubation, or operation |
| 2. Tuberculous ulceration | 8. Lupus of the larynx |
| 3. Syphilitic ulceration | 9. Variolous ulceration |
| 4. Malignant ulceration: | 10. Leprosy of the larynx |
| a. Epitheliomatous | 11. Angioma of the larynx. |
| b. Sarcomatous | |
| 5. Post-typhoidal ulceration | |
| 6. Post-diphtheritic ulceration | |

D. Hæmoptysis due to Changes in the Blood : --

- | | |
|---|--|
| 1. Purpura and its various causes
(p. 675) | 5. Pernicious anæmia |
| 2. Scurvy | 6. Lymphadenoma |
| 3. Splenomedullary leukaemia | 7. Malignant types of specific fevers, such
as variola or measles |
| 4. Lymphatic leukaemia | 8. Hæmophilia. |

E. Doubtful Causes of Hæmoptysis --

- | | |
|---|---|
| 1. Granular kidney | 5. Hæmoptysis in apparently sound and
healthy young subjects |
| 2. Arteriosclerosis | 6. Primary atheroma of the pulmonary
arterioles. |
| 3. Vicarious menstruation | |
| 4. Recurrent hæmoptysis in arthritic
subjects (Andrew Clark) | |

Copious Hæmoptysis has only two causes, namely, *rupture of an aortic aneurysm* into trachea, bronchus, or lung ; and *rupture of an aneurysm of a pulmonary arteriole in a lung cavity or phthisical vomica*. The former, when once it causes severe hæmoptysis, nearly always proves immediately fatal ; the latter may also cause rapid death, but sometimes the severe bleeding stops and recovery may ensue. In either case, however, there is often a stage of slight or premonitory bleeding for days, weeks, or even months before the final rupture occurs.

There are some causes of hæmoptysis in the above list about which little need be said. The whole of Group *E*, for instance, is open to much doubt ; it is true that apparently sound young subjects may have transient hæmoptysis and never develop phthisis ; on the other hand a certain proportion of such cases do become consumptive later, so that the presumption is that in all of them the hæmoptysis really has a tuberculous origin, cure resulting spontaneously in some, but not in others. Particular care should be taken in the examination of the sputum and of the chest by the ordinary physical methods, and by X rays, and even though the cause of the hæmoptysis may not be determined precisely the patient would be well advised to live as healthily as possible, lest a further stage of phthisis develop. The same applies to so-called vicarious menstruation ; and in not a few cases in which the hæmoptysis has been attributed to the arthritic diathesis, to arteriosclerosis, to renal lesions, or to primary atheroma of the pulmonary arterioles, the cause may be really an intercurrent infection of the lung by tubercle bacilli even in middle-aged or elderly people.

Causes in Group *D* seldom give rise to extensive true hæmoptysis, though there may be much epistaxis, bleeding from the gums, and so on. The diagnosis between the different conditions in this group will be found elsewhere.

Phthisis is by far the commonest cause of hæmoptysis. It may be the very first sign of the disease, it may be the last, or it may occur at any intermediate stage. The amount of blood brought up is very variable ; the sputum may be only streaked, or a pint or more may come from the mouth. In advanced stages the diagnosis is not difficult. There is the history of cough, loss of appetite and weight, night sweating, and expectoration ; there are the wasting and flattening of the chest wall, especially above and below the clavicles, often more on one side than the other ; the deficient movement on respiration, the unequal tactile vocal fremitus, the impairment of note, over one upper lobe more than over the other, with the bronchial breathing, consonating râles, bronchophony and pectoriloquy at one apex, with signs of similar but less advanced disease at the other. Detection of pus cells, tubercle bacilli, and perhaps elastic fibres in the sputum, is conclusive. Hæmoptysis may, however, be the earliest evidence of phthisis ; the diagnosis is then difficult, for the physical examination may not reveal any abnormal signs. Particular stress may be laid upon greater prominence of one clavicle than of the other, prolongation of the expiration, and the constant presence of one or more apical clicks, or râles, perhaps brought out only on coughing ; but it cannot be emphasized too strongly that a negative physical examination by no means necessarily implies that early phthisis is not present and active. In some cases the mottled shadows seen with the X rays may assist the diagnosis (*Fig. 117*, p. 133), although, taken by themselves, they may be misleading ; undue shadowing of the lung roots is sometimes regarded as indicative of phthisis, but a great many people exhibit root-shadowings and striations without being consumptive at all ; on the other hand, in the quite early stages of phthisis skiagrams of the chest may seem to indicate perfectly

clear, healthy lungs, for at this stage the degree of change is wholly inadequate to cause opacities that are recognizable with any certainty by present radiographic methods; tubercle bacilli may be found in the sputa quite early, so that a careful examination even of the most insignificant amount of sputum must always be made before a definite opinion as to the cause of hæmoptysis can be given.

In the early stages of phthisis hæmoptysis results from local inflammatory hyperæmia with rupture of capillaries; the amount of blood expectorated is then usually small, and it may amount only to streaking of the sputum. A little later, small vessels may themselves become inflamed and softened, or directly invaded by the tuberculous process, consequently rupturing if any extra strain is suddenly put upon them for instance, during attacks of coughing. This may lead to a more profuse hæmoptysis even quite early in the disease. When the malady is more advanced, caseation and breaking down of lung tissue may lead to softening of the external wall of a considerable branch of the pulmonary artery, resulting in an aneurysmal bulge, which, if thrombosis does not occur within it, will sooner or later rupture, and cause a profuse and possibly fatal hæmorrhage.

Cirrhosis of the Lung Pneumoconiosis, Miner's Phthisis—is a particular variety of fibrosis due to the inhalation of irritating particles, especially amongst workers at certain occupations. Coal miners seldom get it; although their lungs become packed with carbon *anthracosis* these particles do not seem to inflame the tissues. Knife-grinders suffer from it *siderosis*; so do workers in certain limestone quarries, rock-drilling gold mines, and diamond mines *silicosis*. The chief point in the diagnosis is the history as to occupation; there is much doubt as to whether these conditions are not really of a chronic tuberculous nature, and tubercle bacilli should be looked for in all these cases, whilst the blood should also be tested for Wassermann's reaction, because recent evidence points to syphilis being another important factor in some of these patients. The hæmoptysis is far less frequent and less abundant than it is in ordinary phthisis.

Mitral Stenosis is the second commonest cause of hæmoptysis. Other forms of heart disease seldom lead to it direct, though mitral regurgitation may do so occasionally, and so may aortic stenosis or regurgitation when they have caused secondary mitral regurgitation. *Congenital heart disease*, unlike the acquired forms, is so liable to lead to phthisis that any hæmoptysis associated with it would arouse suspicions of the latter. *Fungating endocarditis* may also cause hæmoptysis, but as the result rather of the septic state or of infarction than of the valvular lesion. Mitral stenosis is the chronic valvular heart disease *par excellence* to produce hæmoptysis, and it may do so either when there is complete compensation or when there is evidence of failure. When compensated, the right ventricle pumps blood into the lungs with vigour, and causes great rise of pressure in the pulmonary vessels because the blood cannot escape freely through the stenosed mitral orifice. This is indicated clinically by accentuation or reduplication of the second sound in the second left intercostal space close to the sternum. At the impulse, which is often not materially displaced, the first sound will have a slapping character, and it will generally be preceded by a shorter or longer presystolic rumbling bruit. The latter is so short sometimes that it may be overlooked, but there may be a history of chorea or rheumatism to assist the diagnosis, and the accentuated pulmonary second sound will arouse suspicion in other cases, particularly if the precordial impairment of resonance is increased upwards and to the right, but not much to the left. The result of the great rise of blood-pressure in the lungs is that capillaries rupture from time to time; the resultant hæmoptysis alarms the patient, but it is really no sign of danger, and it may occur when the heart is at its best. Far different is it when blood-spitting occurs in failing cases of mitral stenosis; it is then generally due to infarction or to pulmonary 'apoplexy'. The infarction is less often due to *embolism* from an ante-mortem clot in the right auricular appendix or other part of the right side of the heart than it is to *thrombosis*, due to the combined effects of slowing of the blood-stream and of atheromatous changes in the tunica intima consequent on the strain put on the interior of the pulmonary arterioles by the block to the free egress of blood through the narrowed mitral valve in front of them. An *embolic infarct* occurs suddenly, and causes acute pain in the corresponding part of the thorax, orthopnoea, increased cyanosis, dyspnoea, and hæmoptysis; a *thrombotic infarct* arises gradually, and causes hæmoptysis without the other symptoms.

Violent Coughing Efforts, as in whooping-cough, or emphysema and bronchitis, may cause such pressure of the frænum linguæ against the teeth as to abrade its surface and lead to the expectoration of blood-streaked salivary sputum—spurious hæmoptysis: it is said that they can also produce true hæmoptysis: this is possible, but before blood-spitting in any given case is attributed merely to violence of coughing every care should first be taken to exclude both tubercle and heart disease.

Injury to the Chest is not an uncommon cause of blood-spitting. There need have been no fracture of a rib—a severe blow on the thorax sometimes suffices. The only difficulty in the diagnosis is to be sure that the injury is the sole cause, and that it has not merely been the final factor in producing hæmorrhage from a latent tuberculous focus or an aneurysm.

In **Lobar Pneumonia** the amount of blood expectorated is slight in the majority of cases: the sputum is thick, viscid, tenacious, and generally there is no more blood than will give it a rusty or russet-brown colour. It may, however, be bright red, and in a few cases copious enough to be in itself alarming. The difficulty then is to distinguish it from phthisis, or from lobar pneumonia superposed upon phthisis. The diagnosis is often obvious enough: but sometimes, notwithstanding the acute onset, the continued fever, the high ratio of the respiration to the pulse-rate, the viscosity of the sputum, the presence of capsulated pneumococci in it, the abnormal physical signs, and the absence of chlorides from the urine, serious doubt remains until the subsequent course of the case has been

watched. When the X rays can be utilized at the bedside a skiagram may sometimes serve to differentiate between phthisis (*Figs. 117–119*, pp. 133–135) and lobar pneumonia (*Fig. 297*).

Fig. 297.—Skiagram of lobar pneumonic consolidation of left lung (*A*); normal right lung (*B*); gastric gas-bubble (*C*); liver (*D*).
(By Dr. Alfred C. Jordan.)

Bronchopneumonia is a rare cause of hæmoptysis, because the disease mainly affects children at an age when no spitting occurs. In older patients bronchopneumonia is generally either influenzal, or else due to the inhalation of septic particles from the mouth after operations under anæsthetics, or in association with such diseases as epithelioma of the tongue, or otitis media with lateral sinus thrombosis. Septic bronchopneumonia is diagnosed by reason of its being a lung complication of some other malady likely to give rise to it. *Influenzal bronchopneumonia* in sporadic cases is

apt to cause characteristic sticky râles at the bases, with less pyrexia but more asthenia than does lobar pneumonia: and the minute *Bacilli influenza* may be found in the sputum in large numbers: in times of severe epidemic the pulmonary complications may be excessive, as was the case all over the world in 1918–19, and in such cases hæmoptysis may be pronounced and persistent, though the cyanosis (*Figs. 172–174*, p. 201) is apt to attract still greater notice. A similar state of affairs may present itself in *pneumonic plague*. If the signs are apical rather than basal, it will be difficult to be sure that the condition is not tuberculous, except by watching the case and finding that rapid and complete resolution and recovery ensue.

Gangrene of the Lung, due to whatever cause (p. 322), is characterized by the extreme stench of the breath and sputa. The only conditions which produce similar stench are fetid decomposition of the retained sputum in bronchiectatic cavities or old phthisical vomicae, or similar decomposition in the pus of an empyema which has ruptured through the lung, and which empties out its contents periodically. Gangrene of the lung can be differentiated from these by the pulmonary elastic fibres which are to be found in the sputum.

Infarction of the Lung, embolic or thrombotic, has already been mentioned in connection with heart disease, its most frequent cause. It only remains to add that it may also occur as the result of embolism secondary to thrombosis of systemic veins, infective endocarditis of the pulmonary or tricuspid valves, or from primary thrombosis in some blood diseases, such as leucocythæmia. A large embolus causes sudden death without hæmoptysis: a smaller one may give rise to sudden acute pain in some part of the chest, a local patch of crepitant râles with a pleuritic rub, and perhaps impairment of percussion

note with bronchial breathing. Hæmoptysis associated with such physical signs and accompanied by evidence of endocarditis or venous thrombosis would suggest an infarct : difficulty arises mainly when there is no obvious phlebitis in the case, when the vein affected is deep-seated—in the pelvis, for instance, after childbirth or some operation. The diagnosis is not so difficult when there have been repeated sudden acute pains in different parts of the chest, each followed by a little pyrexia and hæmoptysis, due to repeated small emboli.

Carcinoma and Sarcoma of the Lung (*Fig. 105*, p. 114, and *Fig. 120*, p. 136) are usually secondary. The diagnosis is sometimes obvious, sometimes very obscure. The primary seat of the growth may be near the lung—for instance in a bronchus, the œsophagus, breast, or mediastinal glands : or it may be distant, in the stomach, pancreas, colon, or a bone, and so on. The sputum may be merely blood-tinged, or it may be dark like red-currant jelly : occasionally the hæmorrhage is profuse. Malignant disease in the lung is often accompanied by pleuritic effusion, and unless the existence of a primary neoplasm elsewhere is known growth may not at first be suspected. The fluid is generally found to contain blood : indeed, the discovery of blood-stained pleural fluid at a first tapping of a case that is not absolutely acute is always suggestive of neoplasm : microscopically, large cancer cells, with atypical mitosis, or even fragments of new growth, may be found either in the sputum or in the pleuritic exudate to clinch the diagnosis. Increasing varicosity of the veins on the chest wall, with reversal of the blood current in them, also points to intrathoracic growth obstructing the superior vena cava. The neoplasm may also stenose a bronchus, leading to unilateral deficiency of movement and tactile vocal fremitus, impairment of note, and deficient or absent breath-sounds, with or without faint bronchial breathing and crackling râles : whilst, accompanying these physical signs, no tubercle bacilli would be found in the sputum, and yet the weakness and emaciation would be progressive.

Sporotrichoses of the Lung are generally mistaken at first for phthisis. They are due to various moulds of the nature of *Actinomyces*, *Aspergillus niger*, and others, and the diagnosis depends upon bacteriological investigations of the sputum by cultural methods. When no tubercle bacilli can be detected on repeated examination in the ordinary way, the possibility of sporotrichosis should be borne in mind, particularly if the patient's occupation leads to contact with vegetable products such as hay or straw, grain, bird foods, or cotton as in the case of seamstresses and tailors.

Aortic Aneurysm far less often opens into the lung itself than it does into a bronchus : the symptoms are similar in either case, and if the history is long the diagnosis will already have been made on account of some symptom other than hæmoptysis, especially pain in the chest or in the back. The X rays are a valuable means of deciding the diagnosis (*Fig. 219*, p. 260). Two points are worthy of particular attention, and these are : first, that the rupturing of an aortic aneurysm into a bronchus, with copious and rapidly fatal hæmoptysis, may be the very first sign that anything is wrong : and secondly, that in not a few cases there may have been slight hæmoptysis and blood-streaking of the sputum for weeks or months before the fatal rupture ensues : these preliminary slight attacks of hæmoptysis probably result from turgescence of small vessels in the wall of the bronchus and not from direct leakage of the aneurysm : if the latter is partially obstructing, say, the left upper bronchus, so as to produce impairment of percussion note over the left apex, with a few râles there, and hæmoptysis, it is obvious that a mistaken diagnosis of phthisis might readily be made. Tubercle bacilli will be persistently absent from the sputum, there will in all probability be a previous history of syphilis, hard manual work, and perhaps drinking : without the X rays to show the pulsating shadow of the aneurysm, however, the correct diagnosis may be missed, and even when the fatal rupture occurs the condition may still be erroneously attributed to phthisis unless a post-mortem examination is made.

Empyema bursting through the Lung may or may not cause hæmoptysis : the main features of the case will generally be an obscure febrile illness subsequent to pneumonia, with delay in proper recovery, associated with paroxysms of cough, without much expectoration until during one particularly severe bout the patient suddenly brings up a quantity of pus, and thereafter continues to expectorate pus at longer or shorter intervals : in many cases there are comparatively few abnormal physical signs, for had the empyema not been hidden away deeply in the thorax its existence would have been

diagnosed earlier and it would have been relieved by operation before it burst into the lung.

A Hepatic Abscess that has burst through the lung is apt to give rise to anchovy-sauce-coloured sputum which is characteristic : no amœbæ may be discovered, and the pus will very likely be sterile ; the diagnosis is generally based upon the history of residence in the tropics, possibly of an attack of amœbic dysentery, and of hepatic symptoms, pyrexia, and rigors previous to the expectoration of the blood-stained pus. The abscess occurs on the right side more often than on the left, and there may be the typical dome-shaped dullness in the right axilla or at the base of the right lung.

Hydatid Cysts are much rarer in Europe than in Australia and New Zealand ; those of the lung are, as a rule, secondary to hydatid of the liver. They may give rise to neither signs nor symptoms ; on the other hand, they may cause hæmoptysis, and phthisis may be simulated. The X rays are efficient in detecting their spherical shadows (*Fig. 298*).

The patient's blood may exhibit eosinophilia or the specific hydatid serum reaction.

Hæmoptysis due to changes in the Bronchioles, Bronchi, and Trachea, as distinct from changes in the lung, have to some extent been considered incidentally with the latter.

Bronchitis should never be diagnosed as the cause of hæmoptysis until phthisis and mitral stenosis have been excluded.

Bronchorrhœa is, in most respects, only a variety of bronchitis.

Bronchiectasis may be associated with recurrent slight or even severe hæmoptysis, or when the bronchiectasis is due to obstruction of a bronchus by a thoracic aneurysm there may be copious and fatal hæmoptysis, as described above. Bronchiectasis seldom occurs apart from fibrosis of the lung ; indeed, fibroid lung is commoner than bronchiectasis ; when fibrosis and bronchiectasis occur together and affect one lung in particular, the diagnosis is relatively easy, for there

FIG. 298. Skiagram, taken from behind, of a hydatid cyst of the lung, occupying the position of the upper lobe of the left lung.

is deficiency of bulk, movement, resonance, tactile vocal fremitus, and vesicular murmur over the affected lung : the voice-sounds may be diminished, or they may be unaltered, or increased to bronchophony and pectoriloquy according to the extent to which the alveoli are airless and the bronchial tubes patent or dilated ; the heart is displaced materially towards that side ; râles may be absent, or they may be numerous and crackling over some areas, especially on deep breathing, or after coughing, whilst at the same time there may be little to be heard at all over neighbouring parts of the lung ; the lung on the other side may give relatively normal signs or the signs of compensatory emphysema. The fingers may be clubbed. The diagnosis of fibroid lung and bronchiectasis itself is not complete, however, until the precise cause of the latter has been ascertained : sometimes so complete a diagnosis is not possible. The following is a list of the chief causes of the condition :

1. *Causes in the lung :—*

Congenital atelectasis	Delayed resolution of lobar pneumonia	Chronic tuberculosis
Recurrent attacks of bronchopneumonia	Pneumonoconiosis	Sporotrichosis
		Recurrent bronchitis (doubtful).

2. *Causes which act by partially stenosing a bronchus :* -

a. Causes within the bronchus :

A foreign body
Inspissated bronchitic mucus

b. Causes in the wall of the bronchus :

Syphilitic stenosis
Primary epithelioma

c. Invasion of the bronchus from without :

Aortic aneurysm
Mediastinal new growth
Hodgkin's or lymphadenomatous glands
Caseous bronchial glands
A hypertrophied left auricle in some cases
of mitral stenosis.

3. *Causes which have long compressed the lung from the pleural side :*

Pleuritic effusion

Pleural effusion

Thick pneumonic

lymph

Empyema

A large heart

Pericardial effusion

Ascites

Subdiaphragmatic abscess

Hepatic tumour

Splenic tumour.

There will be no need to discuss each of these here : if the different possibilities are kept in mind a probable diagnosis can be made fairly easily in most cases. Amongst modern methods of diagnosis one must not forget the bronchoscope, through which, in skilled hands, it is often possible to get visual proof of the nature of a tracheal or bronchial obstruction.

Syphilitic Disease of a Bronchus is a tertiary lesion of gummatous nature, and as it heals it causes bronchial stenosis and consequent fibrosis of the lung, with or without bronchiectasis. It will hardly be diagnosed unless there are other very definite means of knowing that the patient has had syphilis, or is still suffering from its tertiary effects, or has a positive Wassermann reaction : and even then care must be taken to exclude the possibility of the luetic patient having developed phthisis. The influence of iodide of potassium, mercury, or salvarsan does not afford conclusive evidence either way, for even though the syphilitic lesion heals it leaves behind it the fibrous stenosis of the bronchus.

The nature of the hæmoptysis caused by *irritant gases* such as chlorine, mustard gas, and allied vapours such as may be employed in war will be obvious from the history.

The **Distoma Pulmonale Westermanni** is an unlikely cause of hæmoptysis in a patient who has not been resident in China, Japan, or Formosa. History of residence in those countries, on the other hand, would suggest the diagnosis, confirmation of which would be afforded by examination of the sputum for the parasites or their ova.

The differential diagnosis of **Hæmoptysis due to changes in the Larynx** depends mainly on two things : the history of the case, and the condition seen locally with the laryngoscope. The history and course are the chief factors in diagnosing acute simple laryngitis, post-typhoidal, post-diphtheritic, or variolous ulceration of the larynx, or conditions due to injury of the larynx by a blow, a hand-grip, a cut throat, or intubation or other operation. Leprous ulceration of the larynx seldom, if ever, occurs in any patient who has not lived in leprosy lands, and who has not for a long time exhibited subcutaneous and cutaneous evidence of his disease. Of the remaining five conditions given in the list, namely, tuberculous, syphilitic, and malignant ulcerations, lupus, and angioma of the larynx, the last two are very rare indeed, though both may be diagnosable by their laryngoscopic appearance, particularly if there is also lupus of the face on the one hand, or a tendency to cutaneous or buccal blood-oozing naevi on the other (*Figs. 299, 300*). Between the remaining three conditions there may be some doubt for a time, but if it can be seen that the ulceration is extensive and yet unilateral it is probably epitheliomatous : if tubercle bacilli are present in the sputum, if there are apical lung signs, and if multiple shallow ulcers can be seen along the epiglottis, as well as in the larynx, tuberculous ulceration is probable - it practically never occurs except secondary to pulmonary tubercle, though the latter may be slight and may remain latent whilst the laryngeal tubercle advances rapidly : syphilitic laryngitis may be diagnosed by exclusion, but if there is a tendency to healing, with marked deformity, after extensive bilateral destruction of the laryngeal and neighbouring tissues, and if there is decided collateral evidence of tertiary syphilis, including a positive Wassermann reaction, the diagnosis may often be made directly. The chief difficulty arises in cases in which there may be both syphilis and tubercle at the same time. This brings us back once more to the fact that, once it has been decided that true hæmoptysis has occurred, the next step is to examine the sputum and the chest carefully for signs of tubercle, and not to diagnose any other condition until both tubercle and mitral stenosis have been excluded.

HEAD, RETRACTION OF. (See RETRACTION OF THE HEAD, p. 731.)

HEADACHE may be of minor significance in many cases, but on the other hand it may be the first symptom calling attention to the existence of grave organic disease, and the correct diagnosis of the cause is obviously important. Symptomatic treatment of a headache should never precede a careful investigation of the case with the object of either excluding or of recognizing one or other of its more serious causes.

The explanation of the mode of production of the pain known as *headache* is not easy, seeing that the brain substance itself is insensible to mechanical stimulation. The meninges are supplied with sensory nerves, and abnormal stimuli received therefrom reach the cortex and give rise to the impression of pain. Abnormal states of the intracranial blood-vessels may cause pain, which is more difficult of explanation, as it is uncertain that they have any sensory nerve-supply. It seems probable that the headache produced by increased vascular tension is a pressure effect acting on the brain as a whole, or on its coverings the meninges. The scope of this article does not allow further discussion of this part of the subject. Certain general lines of diagnosis may be laid down. The closest attention should be paid to the character, situation, and time of occurrence of the pain, and also to accompanying symptoms.

Character. Whether throbbing, paroxysmal, or affected by movement or position. Headaches associated with alimentary disturbance, or raised blood-pressure, are often throbbing in character, are relieved by rest in a recumbent position, and are increased on movement. Severe paroxysmal attacks may be due to neuralgia.

Situation. This may be frontal, vertical, occipital, or unilateral, and in cases of organic disease of the cerebrum may be an important indication and an aid in localizing the situation of the lesion. In renal disease the headache associated with chronic uræmia is usually frontal, but may be occipital. It is vertical in constipation, the 'bilious' headache. It may be unilateral in migraine, tumour, abscess, middle-ear disease; or occipital in cerebellar disease. Occipital headache may also be simulated by myalgia in the muscles and tendons of the nape of the neck. Purely frontal headache is suggestive of catarrh in the frontal sinuses, though it is also familiar as a sequela of malaria 'brow ague'.

Time of Occurrence. Headache associated with organic disease of the brain or its meninges often persists or becomes worse at night, and may wake the patient from his

sleep, whereas that due to toxic and functional causes is relieved by rest in a horizontal position. Grave suspicion of the organic nature of the headache should, therefore, attend a case in which pain in the head disturbs the patient's sleep at night. A headache experienced on rising in the morning may be due to a stuffy, ill-ventilated room, to the effects of coal gas leaking perhaps imperceptibly from the pipe, to the fumes of a coke stove or gas fire, or to the slighter degrees of combined astigmatism and hypermetropia. Pillows piled too high may cause interference with the cerebral circulation and result in headache. Persistent morning headache may be associated with chronic nephritis, and careful observation should therefore be made of the patient's urine. *Evening* headaches are most commonly due to mental overwork, or eyestrain, especially where some visual defect exists.

For the purposes of classification it is convenient to divide the causes of headache into three main groups: (A) *Organic disease* (brain, intracranial vessels, meninges, skull, special sense organs); (B) *Toxic states*; (C) *Functional conditions*.

A. Causes due to Organic Disease.--

These may be classified anatomically as follows:--

1. Diseases of the brain:--

Concussion	Gumma	Hydrocephaly	General paralysis of the insane.
Tumour	Cyst	Disseminated sclerosis	
Abscess	Encephalitis lethargica	Abnormal conditions of the pituitary gland	

2. Diseases of intracranial vessels:--

Hæmorrhage (rupture)	Thrombosis Embolism	Aneurysm Syphilitic endarteritis	Arteriosclerosis.
-------------------------	------------------------	-------------------------------------	-------------------

3. Diseases of the meninges:--

Meningitis, various forms localized or diffuse	Pachymeningitis Syphilis meningeal type	Tumour Cyst.
---	--	-----------------

4. Diseases of the skull:--

Tumours	(Innocent	(Primary
	(Malignant	(Secondary
Tertiary syphilis		
Suppuration or new growth in frontal, antral, or mastoid sinuses		
Suppuration or tumour in the orbit		
Dental diseases.		

5. Diseases of special sense organs:

Eye--errors of refraction, iritis, glaucoma, conjunctivitis, melanotic sarcoma
Ear--middle-ear disease
Nose--adenoids, polypi, nasopharyngeal catarrh. Inflammation of one of the accessory air sinuses--frontal, ethmoidal, sphenoidal: empyema of a frontal sinus.

HEADACHE IN ORGANIC CEREBRAL DISEASE.

Time of Occurrence. Organic cerebral disease should be suspected if a history of recurrent nocturnal headache be obtained.

Severity. The pain is often intense, and sometimes paroxysmal in character.

Situation. This may give some clue as to the existence of an organic lesion. In cases of cerebral tumour the pain may be unilateral or frontal, or occipital with a cerebellar lesion. In middle-ear and mastoid disease with unilateral headache and localized tenderness, occipital headache may be one of the earliest symptoms of meningitis.

Associated Signs and Symptoms. One or more of the following signs and symptoms may present themselves at an early period in cases of headache due to organic cerebral disease, and their early recognition is of great importance:--

Vomiting--that is of the 'cerebral type' (see VOMITING, p. 927): it usually bears no relation to food, and is not preceded by nausea	Squint
Inequality of the pupils	Optic neuritis (<i>Figs.</i> 418, 419, p. 518)
	Drowsiness
	Twitchings
	Convulsions.

Tapping the skull over the site of the pain may reveal local tenderness.

The onset of any of these signs associated with headache would point to the existence of one or other of the organic lesions enumerated above : ophthalmoscopic examination for optic neuritis is essential ; lumbar puncture and investigation of the cerebrospinal fluid is often necessary (p. 382) ; and the differential diagnosis depends on experience in interpreting the findings.

The headache occasionally met with in *disseminated sclerosis* is sometimes paroxysmal and accompanied by vomiting, and is situated most frequently in the back of the head and neck. The absence of optic neuritis serves to exclude *cerebellar tumour* or *abscess*, which might be alternative diagnoses suggested by the nystagmus, intention tremors, and ataxy.

Cerebral hæmorrhage, thrombosis, and embolism are often followed by headache of varying severity. With *cerebral aneurysm* a rhythmic beating or pulsation may be complained of and rushing noises are heard, more particularly when the internal carotid is involved, but such throbbings are commoner as the result of *atheroma, arteriosclerosis, and high blood-pressure*. Similar rhythmic beatings or noises in the head are common also in many anæmic persons.

Advanced *arteriosclerosis* is sometimes attended by severe headache accompanied by vomiting ; and cases have been described presenting features closely resembling those of cerebral tumour. The difficulty is increased when, as part of albuminuric retinitis, there is definite optic neuritis although no cerebral tumour is present. In arriving at the diagnosis instrumental measurement of the blood-pressure is all-important. *Plumbism* may also cause optic neuritis simulating cerebral tumour (see *Fig. 135*, p. 156).

In *meningitis*, especially in the epidemic cerebrospinal and the post-basal varieties, the character of the headache is significant. It is usually intense, occipital, and even at an early stage attended by stiffness of the neck and retraction of the head. Examination of the cerebrospinal fluid (p. 382) obtained by lumbar puncture is important in determining the presence of meningitis.

Headache due to *sinus disease* may present the following characteristics. It may be induced or increased by certain movements such as stooping. It may be worse in the morning than in the evening. It may be unilateral and periodical in occurrence.

Lumbar puncture for diagnostic purposes or for the administration of serum or a spinal anæsthetic may be followed by severe headache which is usually relieved by absolute rest in the recumbent position without pillows.

Special Sense Organs : Eye. Headaches due to errors of refraction, glaucoma, iritis, etc., are generally frontal or temporal. A slight error of refraction may cause what appears to be a disproportionately severe headache, particularly in children. This headache is frontal, occurs mostly in the evening or after school hours, and is often attended by a burning, pricking, or watering of the eyes. Correction of the defect by suitable glasses settles the diagnosis by curing the headache.

B. Toxic Causes.—

These may be subdivided into two groups : (1) That in which the toxic influence is acquired from without, *exogenous* ; (2) That in which the disturbing element or toxin is produced within the body, *endogenous*.

1. Of *exogenous* origin :

Foul air, as in close, ill-ventilated rooms, exhaust gases from motor cars		
Poisonous gases, CO ₂ , CO, chloroform, ether, coal gas, acetone, etc.		
Drugs, e.g., quinine, iron in some individuals, salicylates, opium		
Alcohol	Tobacco	Lead poisoning
Malaria,		

2. Of *endogenous* origin :

Uremia	Gout
Cholemia	Diabetes
Gastro-intestinal disturbances : dyspepsia, constipation, acidosis	
Toxæmias : specific fevers, especially typhoid ; pulmonary tuberculosis with pyrexia suppurative, etc.	

As regards the *toxic causes* of headache little need be said as to the diagnosis of the exogenous poisons except perhaps to emphasize the fact that unless they are remembered

as a possibility a patient may be thought to have a cerebral tumour when the real cause may be, for instance, a badly ventilated gas-fire.

Of the endogenous causes, *uræmia* stands out as one of the most important. Uræmic headaches may be of all degrees of severity, from a slight frontal headache felt on rising in the morning to an intense vertical or general cephalgia. Other uræmic manifestations may be present, such as vomiting, drowsiness, dyspnoea, affections of vision, and retinal changes. Examination of the urine in all cases of headache should never be neglected, as regards its specific gravity, the presence of albumin, blood, and casts.

C. Functional Causes.

Abnormal blood-pressure	(high, in arteriosclerosis and renal disease (low, in anæmia, morbus cordis, Addison's disease)
Venous congestion	Menstruation
Excessive mental strain	Hysteria ('clavus hystericus')
Pressure on the head—heavy hats, carrying weights on the head	Migraine
Persistent noises—'gun headache'	Recurrent sick-headache
Sea-sickness—movement of boat, train, motor car	Epilepsy
	Eyestrain, 'academy headache'
	Sunstroke.

High blood-pressure is often a cause of headache, usually of a throbbing character, accompanied by a sense of fullness of the head. The headache tends to come on towards evening and after meals. The vascular condition is indicated by the sphygmomanometer.

Headache associated with *low blood-pressure* (cerebral anæmia), as in some forms of morbus cordis and anæmia with feeble cardiac action, is relieved by rest in the horizontal position and cardiac tonics such as digitalis and iron.

Venous congestion may cause headache. This is also met with in heart disease with failing compensation. It may also account for the headache felt on rising in the morning as the result of sleeping with pillows too high or too low.

The '*clavus hystericus*' is a boring pain felt in the vertex and in hysterical states.

Headache in *migraine* is often unilateral, though quite commonly bilateral, and frequently it is accompanied by vomiting. Transitory visual disturbance usually precedes the headache.

In *epilepsy* headache is of frequent occurrence in the post-epileptic state, and it should be borne in mind that it may also follow the slight manifestations of *petit mal*.

After *sunstroke*, chronic headache, usually vertical, may persist for months, and the same applies to many head injuries.

It is sometimes difficult to distinguish between *headache*, which implies pain inside the skull, and *neuralgia*, which is pain felt in the peripheral course of a nerve trunk (see PAIN IN THE FACE, p. 548). Neuralgia, if of wide distribution, may simulate headache. Careful examination may be necessary to decide whether the supposed headache may not in reality be a neuralgia. The local distribution, the often intense and paroxysmal character of the pain, the presence of 'tender spots,' the existence of some definite exciting cause such as dental caries, should point to the diagnosis of neuralgia.

H. Morley Fletcher.

HEART, ENLARGEMENT OF. (See ENLARGEMENT OF THE HEART, p. 257.)

HEART IMPULSE, DISPLACED.—The apex beat, which is the lowest and outermost point at which the cardiac impulse can be felt, is situated in the normal adult chest in the fifth left intercostal space, one-half to one inch internal to the mammary line. It may be impossible to define the position of the apex beat even in health on account of increased thickness of the chest wall either from muscular development or excess of fat; or in the female on account of a large mamma. A similar difficulty arises when the cardiac impulse is feeble; when the heart is overlapped by an emphysematous left lung; or when pericardial effusion is present. In children the apex beat is situated farther to the left and a little higher than in adults; speaking generally, it is outside the mammary line during the first three years of life, in the mammary line from the fourth to the tenth years, and it gradually reaches the adult position by the age of fifteen.

The conditions which produce displacement of the cardiac impulse are:—

A. WHEN THE BULK OF THE HEART IS IN THE NORMAL POSITION.

1. *Diseases of the heart* : —(a) Valvular ; (b) Myocardial ; (c) Pericardial.
2. *Changes in the heart secondary to* : —(a) Diseases of the lungs, such as emphysema, fibrosis, etc. ; (b) Arterial sclerosis and chronic renal disease ; (c) Anæmia and debilitating conditions, affecting chiefly the right ventricle ; (d) Toxic conditions producing myocardial changes, as in infective diseases ; (e) Muscular exertion.

B. WHEN THE WHOLE HEART IS DISPLACED.

1. *Changes in the lungs* : (a) Contraction of one lung or a portion of it, especially by fibroid lung, with or without bronchiectasis ; (b) New growth of lung ; (c) Massive collapse of the lung.
2. *Changes in the pleura* : (a) Pleurisy with effusion, empyema, pneumothorax ; (b) New growth of pleura.
3. *Other thoracic tumours* : —Mediastinal new growth ; aortic aneurysm.
4. *Deformities of the chest wall* : The result of scoliosis, injury, operation.
5. *Changes in the abdomen* : Ascites ; tympanites ; abdominal tumour ; pregnancy.
6. *Congenital transposition of the heart.*

To distinguish between the two groups is usually not difficult :—

1. When the Bulk of the Heart is in the Normal Position and the apex beat is displaced beyond the left mammary line, the area of cardiac dullness is increased, not only to the left, but also to the right of the sternum, and upward. If both lungs are emphysematous and the cardiac apex is displaced outwards, although the size of the heart cannot be estimated by percussion, yet the bulk of the heart may be presumed to be in the normal position.

The presence of a cardiac valvular lesion, arterial sclerosis, high blood-pressure, or chronic renal disease helps to confirm the view that the abnormal position of the apex beat is due to an increase in the bulk of the heart, and not to a displacement of the organ as a whole.

The presence of a cardiac bruit is of great value in determining that the displaced apex is due to morbid changes in the heart ; but the absence of a bruit does not necessarily mean that the displaced apex beat is unassociated with cardiac disease. The enlargement of the left ventricle due to arterial degeneration or chronic interstitial nephritis may not be accompanied by any bruit unless dilatation becomes so great that mitral regurgitation supervenes. The characters of any of the cardiac sounds are frequently altered in dilatation and hypertrophy of the left ventricle. Thus, the aortic second sound may be accentuated on account of the increased arterial tension, and the second sound over the base of the heart may be reduplicated on account of the aortic and pulmonary valves not closing synchronously. The first sound is frequently louder and more prolonged than normal at the impulse when there is hypertrophy of the left ventricle, due to an increase in the muscular element of the sound. The existence of cardiac hypertrophy and dilatation may be less certain when there is neither bruit nor raised blood-pressure, for instance, in the case of certain *alcoholic hearts*, or of *sypilitic hearts* with myocardial changes without valvular disease ; it may be necessary to X-ray the chest to determine the exact cardiac dimensions : the transverse diameter of the cardiac shadow should not exceed $6\frac{3}{4}$ in. at its widest part, whereas sometimes a skiagram may show the heart to be far greater than this — even perhaps up to 10 in. in transverse width. The X rays are a valuable means of deciding the precise size of the heart (*Figs. 301-303*).

When there is pericarditis, the cardiac impulse may be displaced to the left owing to dilatation, but the diagnosis will be indicated by the pericardial friction sounds or by the canter rhythm ; these do not disappear when pericardial effusion ensues unless this is suppurative, when the diagnosis may be extremely difficult. With pericardial effusion the impulse is apt to be displaced outwards and upwards instead of downwards, and may lie in the fourth space external to the left nipple.

The direction in which the apex beat is displaced may be of diagnostic value. It is displaced downwards and to the left in *hypertrophy of the heart*, especially when it affects chiefly the left ventricle. In *mitral regurgitation* the apex beat is displaced outwards and to the left, whereas in *lesions of the aortic valves* the displacement is to the left and downwards, so that the apex beat is commonly situated in the sixth intercostal space. In both these conditions the left ventricle is enlarged, but with mitral regurgitation the right side of the heart becomes enlarged early in the disease, and the apex is displaced much more outwards than downwards. When the *right ventricle alone is enlarged*, as in pulmonary emphysema or chronic bronchitis, the displacement of the apex beat may be directly to the left, and not downwards at all.

Fig. 301.—Skiergram of a normal chest, showing clear lungs, a minor degree of root shadowing and mottling not indicating disease, and a normal-sized heart in an adult. The figure has been reversed in the making. (By Dr. E. Talbot Noddy.)

It is raised and displaced slightly to the left by any cause which increases the height of the diaphragm, such as ascites, tympanites, abdominal tumours, and pregnancy. The cardiac impulse is also raised by pericardial effusion. The apex beat may be found to be displaced slightly outwards in many young adult males without any apparent cause; if the subject be a muscular man in apparently perfect

health, the condition is probably due to hypertrophy of the left ventricle as the result of *athletic exercise* or of some arduous muscular work; the condition is familiar in rowing men, gymnasts, blacksmiths, navvies, and the like. The history would suggest the diagnosis. If, on the other hand, the patient is not a muscular person, the displacement may still be due to physical causes; but some other cause should always be looked for, and in the absence of any obvious cardiac lesion the effects of recent illness, or of persistent toxæmia from teeth, urine, bowel, or elsewhere, with concomitant myocardial changes, need to be considered; *cardiac adhesions* must not be forgotten; these may produce few symptoms except slight enlargement of the heart.

In girls the apex beat is often situated in the mammary line, and this displacement is associated with *chlorosis* and other debilitating conditions; the anæmic state may be associated with a functional systolic bruit in the pulmonary area and a *bruit de diable* in the neck.

In elderly people in whom there is no valvular disease of the heart, the apex may be displaced not only as the result of hypertrophy of the left ventricle secondary to renal disease and arterial sclerosis, or as the result of enlargement of the right ventricle secondary to pulmonary emphysema, but also as the result of *fibroid* or *fatty myocardial*

Fig. 302.—Skiergram showing great enlargement of the heart as the result of post-rheumatic mitral valvular disease. Compare with Fig. 301, which shows the size of a normal heart. (By Dr. C. Thurston Holland.)

As the result of enlargement of the right ventricle secondary to pulmonary emphysema, but also as the result of *fibroid* or *fatty myocardial*

degeneration or of *coronary artery sclerosis*. The last condition may be difficult of diagnosis, but when there is no evidence of valvular disease, emphysema, chronic renal disease, arterial sclerosis, high blood-pressure, or anything causing displacement of the heart as a whole, it may be suspected when a seemingly healthy patient, no longer young, is subject to dyspnoea upon exertion, attacks of syncope, palpitation, precordial pain, or angina pectoris. The patient may complain of little when walking upon level ground, but gets the symptoms whenever he goes up even a slight incline, or hurries in his pace.

Another form of uniform cardiac hypertrophy that needs special mention is that which results from long-continued drinking of large quantities of fluid, particularly beer—the *beer-drinker's heart*.

B. When the Whole Heart is Displaced. In the second class of cases, the cause of the displacement is usually easy to ascertain. The chest is frequently asymmetrical, either bulging on the side from which the heart is displaced, or shrunken on the side to which it is drawn. Percussion may show that resonance is present where normally there is cardiac dullness: thus, when the left lung is fibroid and the heart is pulled over to the left, the resonance of the right lung may be found extending to the left of the sternum; whilst alternatively, when the right lung is fibrous, the whole of the ordinary precordia may be resonant and the heart dullness lie entirely to the right of the sternum as though there were true dextrocardia; the impaired note at the right base behind will then give the clue to the diagnosis.

It is not always so easy to determine the boundaries of the heart when the displacement is due to the presence of a *pleural effusion*, as there is dullness over the effusion which may be continuous with the cardiac dullness. In such a case, however, the dullness over the base of the lung behind, with deficient or absent breath-sounds and voice-sounds, will suggest pleural or pleuritic effusion, and the displacement of the cardiac impulse towards the opposite side is a valuable sign confirmatory of fluid in the chest on the dull side. When the heart is drawn over by a contracted *fibroid lung*, the impaired resonance upon percussion over the fibrosed lung is at the base of the same side as that towards which the heart is drawn, whilst the resonance over the healthy other lung will often extend across the middle line and thus invade the normal position of cardiac dullness.

Massive collapse of the lung is met with mainly after abdominal operations which involve extensive manipulation of the liver or which otherwise interfere with the diaphragm: it is also met with after violent injury to the trunk. The right lung is affected more often than the left: the lower half of the right thorax becomes dull to percussion, and there may be stethoscopic silence suggesting pleurisy with effusion, or definite bronchial breathing, bronchophony, and pectoriloquy suggesting lobar pneumonia: both these diagnoses are put out of count, however, when it is found that the cardiac impulse has become displaced well over to the dull side—a fact that at once suggests massive pulmonary collapse as the

FIG. 366.—Skiagraph illustrating two demonstrable effects of pleural effusion: at the base of the line, in this instance on the patient's right side, namely, smoothness of the outline of the cupola of the diaphragm, which should be smoothly rounded; and obscuration of the costo-phrenic angle, which should be bright and clear.

The skiagraph also serves as an illustration of the skiagraphic appearance of a normal adult heart. (See Dr. W. H. Coldwell.)

cause of the abnormal signs. The collapse clears up in a few days and the heart returns to its normal position, if the patient does not die.

The *changes in the abdomen* causing displacement of the heart upwards are not likely to be overlooked, because there must be great abdominal enlargement before the heart can be thus pushed up : if displacements of the apex beat are due to ascites, tympanites, abdominal tumours, or pregnancy, the latter are of such a degree that they are obvious. Rarities such as *hernia of the stomach through the diaphragm* may be suggested by special circumstances in the case—the history of previous bullet wound of the thorax which may have lacerated the diaphragm, for instance : and may be confirmed by special methods, such as skiagraphy after a bismuth meal (*Fig. 514*, p. 649).

Herbert French.

HEART SOUNDS.—(See BRUITS, CARDIAC, p. 116.)

HEART SOUNDS, ACCENTUATION OF. (See ACCENTUATION OF HEART SOUNDS, p. 1.)

HEART SOUNDS, REDUPLICATION OF.—(See REDUPLICATION OF HEART SOUND, p. 729.)

HEARTBURN is a common symptom, yet difficult to define. Apparently it is due to regurgitation into the lower end of the œsophagus from the stomach of acid products of digestion, and it is thus related to pyrosis or waterbrash, in which similar acid products regurgitate suddenly as far up as the upper end of the pharynx and the back of the mouth, causing a local sense of burning acidity in the throat, and often a temporary huskiness of the voice. Neither waterbrash nor heartburn is distinctive of any particular malady. Either may occur in a perfectly healthy individual who for some transient digestive cause has rather more gas in his stomach than the latter can hold comfortably : with the escape of some of this gas a drachm or two of the liquid gastric contents may be shot up into the lower end of the œsophagus to cause heartburn, or further up still to cause waterbrash. On the other hand, if the symptoms are persistently troublesome either may indicate more serious lesions, such as flatulent dyspepsia (see FLATULENCE, p. 302), or pyloric stenosis from healed ulcer or gastric carcinoma (see DILATATION OF THE STOMACH, p. 218). If the symptoms are obviously not transient, analyses of test meals (pp. 344 and 400) or X-ray examination of the stomach (*Figs. 276–283*, pp. 339–343) may be required before the diagnosis of their cause can be established. Duodenal ulcer, gall-stone dyspepsia, appendix dyspepsia, ileo-cæcal kinking, visceroptosis, gastro-intestinal neurosis, and the excessive smoking of tobacco will also need to be borne in mind as possibilities.

The actual symptoms of heartburn take two forms. The first consists in a more or less acute pain, sometimes of a really burning character, more often of a severe aching, boring, or even lancinating type, referred to the mid-line of the lower end of the gladiolus, especially between the two fifth costal cartilages, coming on as a rule an hour or more after dinner when digestion is at its height, beginning either gradually or suddenly, often increasing in severity for half an hour or an hour, and lasting sometimes for several hours or a whole day : this is generally referable to its cause—flatulence—with ease, especially if simple treatment with bicarbonate of soda and rhubarb relieves the pain. The other type consists in attacks of acute gripping pain in the precordial region, especially near the apex of the heart : this pain comes on quite suddenly and often lasts less than a minute and seldom more than a few minutes. While it is there the patient may find himself unable to take an ordinary breath without increasing the pain to an unbearable extent : he therefore holds his breath entirely for as long as he can, generally presses a hand over the precordial region, and when he is compelled to inspire again he finds that he gets checked before he has breathed in as much air as he would like to : he therefore contents himself for a minute or two with a minimum depth of breathing, by which time the acute precordial pain passes off and he is able to breathe normally again. The attack may be repeated after an interval of minutes or hours : there is often no palpitation, but in some cases severe palpitations accompany or follow the pain, and the main difficulty is to exclude organic heart disease which the patient fears his symptoms indicate. When the attacks are only occasional, and there is no shortness of breath, gastric disorder is more probable than heart trouble : when, however, the attacks are frequent and the patient

is out of condition, it may require skilful judgement to decide that the attacks of precordial colic are of gastric and not cardiac origin. Fatty, fibroid, alcoholic, or tobacco hearts are the most difficult to exclude; the relief the patient receives from carminatives such as bicarbonate of soda, gentian, cajuput oil, ginger, rhubarb, peppermint, does not necessarily indicate that the trouble is primarily gastric; and even when the fullest examinations have been made, including the use of the electrocardiograph, there are many instances in which it remains very much a matter of opinion whether the attacks are due to myocardial changes or to the much less serious heartburn.

Herbert French.

HEEL, PAIN IN. (See PAIN IN THE HEEL, p. 551.)

HEMERALOPIA. (See VISION, DEFECTS OF, p. 920.)

HEMIANÆSTHESIA. (See SENSATION, SOME ABNORMALITIES OF, p. 747.)

HEMIANOPSIA or, as it is sometimes called, *hemipopia* or *hemianopia*—means inability to see objects in one half of the field of vision. It is generally, but arbitrarily, restricted to cases in which this defect is due to changes elsewhere than in the retina or disc. It is not common, but it sometimes escapes recognition because, whichever half of the visual field has become blind, good vision remains at the central part, and the patient may not be conscious of his defect until some accident, such as running into objects in

Fig. 294. Fig. 295. Diagram showing how a tumour of the pituitary body affecting the decussating fibres at the optic chiasm prevents impulses passing from the nasal half of either retina to the corresponding cortex or to the corresponding third nucleus. Hence bilateral temporal hemianopia and absence of pupal reaction to light thrown on the nasal half of either retina.

broad daylight, draws his attention to it. To map out the blind area with accuracy the perimeter is required.

Hemianopsia in one eye only is rare apart from functional conditions or migraine; but it is met with sometimes in those who have ascended to great heights, either as mountaineers or in aeroplanes—*altitudinal hemianopsia*.

When both eyes are affected, the blindness may affect: (1) Opposite halves of the field of vision—almost invariably the temporal halves, and referred to as *bilateral temporal hemianopsia* (Figs. 305 and 306); or (2) Corresponding halves of the field of vision—

Fig. 306.—Perimeter chart showing bilateral temporal hemianopsia due to enlargement of the pituitary body in acromegaly. The blackened areas indicate the parts of the field of vision that had become blind (compare Fig. 305). The eccentric line indicates the average normal field of indirect vision.

bilateral homonymous hemianopsia—spoken of as *right* if neither eye can see objects in the patient's right-hand half of the field of vision (Figs. 311, 312, and 313), and as *left* if in the left half. These are the two varieties of clinical importance; they are generally not the only symptoms in the case, but they sometimes serve to localize certain cranial lesions with accuracy.

Bilateral Temporal Hemianopsia.—There is only one spot at which a single lesion can produce this condition; this is at the central part of the optic chiasma, where the fibres

Fig. 307.—Skiagram showing a normal pituitary fossa in an adult. The arrow points to the base of the pituitary fossa. (By Dr. W. H. Coldwell.)

from the nasal half of each eye are decussating. The three commonest causes of this rare lesion are: (a) Hypertrophy of the pituitary body (Figs. 307-310), a condition which also leads to acromegaly or to gigantism, so that it is important to test for bilateral

temporal hemianopsia in every case of acromegaly, and it will be found in a certain number; (b) Callus, resulting from a fracture of the base of the skull through the basisphenoid bone; (c) A gumma or other tumour in this region. The differential diagnosis between these three groups will generally be obvious enough when the variety of hemianopsia has been established.

Bilateral Homonymous Hemianopsia has a variety of causes, affecting one or other of three main sites, namely: (a) One optic tract; (b) The posterior limb of one internal capsule; or (c) The optic radiations, or one occipital region at or near the cuneus. In any of these sites the pathological lesion may be either vascular, thrombosis, hemorrhage, embolism, or intermittent claudication; or a neoplasm, such as a gumma, a tuberculous nodule, an inflammatory swelling, or a gliomatous, carcinomatous, or sarcomatous nodule. The first step is to locate the site of the lesion; its nature will then be determined more easily, because in the internal capsule a hemorrhage, thrombosis, or embolism of the middle cerebral artery is the commonest cause of the symptom; a neoplasm, or an abscess, is probably its commonest cause in the occipital cortex, though rupture or occlusion of the posterior cerebral artery would also be thought of; in the optic tract it is as often as not gliomatous, or in some other way syphilitic.

In order to decide the locality of the lesion, it is essential in the first place to determine

whether a pencil of light falling upon that part of the retina which cannot see is able to evoke a reflex contraction of the pupil. This requires careful testing in a dark room, with a small pencil of light directed towards different portions of the eye at the observer's will by a suitable mirror or lens. Anatomical considerations make it obvious that if the optic tract is destroyed there is no path by which the light impulses from the non-seeing portions of retina can reach the oculomotor nucleus, so that there will be no reflex movement of the pupil in response to light (*Fig. 311*). If, on the

other hand, the optic tract is intact, the lesion being in the posterior limb of the internal capsule, or in the optic radiations or the cuneus, the same hemianopsia results, but the pupils react to light stimuli falling upon the blind halves of the retinae (*Fig. 312*). If the light reflex is lost the lesion is at once located to the optic tract, provided there is no obvious trouble, such as cataract, locomotor ataxy, or iritic adhesions, to prevent the reaction. If, on the other hand, the light reflex remains, the lesion must be in one of the three other places mentioned, and in determining this the history may help considerably. If there has been an apoplectic seizure in an elderly person, hemorrhage in the region of the internal capsule is likely, and there will often be both hemiparesis and hemiparæsthesia

at the same time. In a younger person suffering from heart disease, a somewhat similar history would point to embolism involving the posterior limb of the internal capsule.

Fig. 311. Diagram showing how a lesion of the left optic tract causes blindness of the right half of the field of vision of each eye, and also prevents the left pupil from reacting in response to a ray of light falling on the blind half of either retina.

Fig. 312. Diagram showing how a lesion of the left optic radiation causes blindness of the right half of the field of vision of each eye, but does not prevent the pupils from reacting in response to a ray of light falling on the blind half of either retina.

If, on the other hand, there has been a slow onset, with increasing headache, vomiting, and giddiness, then either syphilitic endarteritis with thrombosis, or a neoplasm or gumma affecting the optic radiations or one occipital pole will be not unlikely.

Fig. 313. Perimeter chart showing bilateral homonymous hemianopsia resulting from bilateral embolism of the optic radiations (compare Fig. 312).

If the patient is unable to see things in the right halves of his fields of vision, the lesion will be in his left optic tract, left internal capsule, left optic radiations, or left cuneus, as the case may be, and vice versa.

Hemianopsia due to migraine or to intermittent closure of cerebral vessels will be distinguished from that due to the other causes by its presence on some occasions and its absence on others.

Irregular or partial forms of hemianopsia result from irregular or partial lesions in the optic tract or other regions mentioned above. The differential diagnosis is then more difficult, though it is made upon the same lines as those described above. From a diagnostic point of view it is fortunate perhaps that hemianopsia, when it occurs at all, is generally definite, and either bilateral temporal or bilateral homonymous. *Herbert French.*

HEMIPLEGIA signifies loss of motor power in the limbs of one side: the face, especially its lower half, being affected frequently at the same time. In the great majority of cases the face is paretic on the same side as the affected arm and leg, but there is one important exception, namely, when the lesion is in one side of the pons Varolii, when there is paralysis of the face upon the same side as the lesion, and of the arm and leg upon the opposite side—a condition known as *crossed hemiplegia*. The lesion in most cases, however, is in or near the internal capsule, less often in the motor cortex, of the opposite side to that which is hemiplegic. There may or may not be hemianæsthesia (p. 753): and in rare cases, when the lesion is far back in the internal capsule, there may also be HEMI-ANOPSIA (p. 377). When the cause lies in the internal capsule the paralysed muscles may be either flaccid or spastic, but they do not as a rule exhibit the athetotic and other involuntary movements that cortical lesions may give rise to (see CONTRACTIONS, p. 168). When a patient has difficulty in speech associated with hemiplegia, it is important to distinguish dysarthria from aphasia (see SPEECH, ABNORMALITIES OF, p. 769). Lesions of the internal capsule often produce difficulty in using the tongue, which renders speech mechanically difficult (dysarthria)—a very different thing from the aphasia or difficulty in uttering the correct words when the mechanism for the movements of the tongue is unaffected. True aphasia associated with hemiplegia suggests a lesion at, or close to, Broca's area of the cortex on the left side, and is therefore less common with left-sided than with right-sided hemiplegia.

The fact of hemiplegia is generally not difficult to determine, though in some cases there may be so slight a weakness that doubts arise. Routine examination of such a patient will generally detect a little inequality in the degree to which the eyes can be closed firmly, a slight difference in the depth of the two nasolabial folds when the patient opens his lips with his teeth clenched, a greater difference than previously between the two hand-grips, slightly brisker radial and ulnar wrist-jerks, or tricipital and bicipital elbow-jerks upon the affected side, inequality of the knee-jerks with a tendency to exaggeration upon the paretic side, with corresponding extensor-plantar reflex and increased Achillis jerk or even ankle-clonus. All these changes will be pronounced in cases where the hemiplegia is more definite, though if the patient be seen within a short time of the onset of hemiplegia from cerebral hamorrhage, the tendon and other reflexes—which will presently be exaggerated should the patient survive—may for the time being be decreased or even unobtainable upon the affected side.

Stress is often laid upon the presence or absence of rigidity in connection with hemiplegia, particularly according as the rigidity comes on early or late in the case. This helps less, however, in the diagnosis than it does in the prognosis. A few cases of hemiplegia are flaccid throughout, though this is uncommon if the patient survives and the hemiplegia persists: in cases of hemiplegia due to cerebral hamorrhage, early rigidity generally suggests a smaller hamorrhage than does early flaccidity followed by rigidity: so variable is this, however, that the point is of less value than has sometimes been supposed.

The causes of hemiplegia may be summarized as follows:

1. THE COMMONER CAUSES OF HEMIPLEGIA.

1. Hemiplegia of Moderately Rapid Onset.

Cerebral hamorrhage	(Syphilitic endarteritis of a middle cerebral
Thrombosis of a middle cerebral artery	(artery.

2. Hemiplegia of Sudden Onset.

Embolism of the middle cerebral artery, generally due to mitral stenosis, or to fungating endocarditis.

3. Hemiplegia dating from Birth, or from infancy, and resulting from :

Injury	Sinus thrombosis
Congenital malformation	Meningococcal meningitis.
Acute encephalitis	

B.—LESS USUAL CAUSES OF HEMIPLEGIA.

General paralysis of the insane	Stab or bullet wound injuring the spinal cord in the cervical region
Borderland sufficiency of the cerebral circulation in old people (intermittent claudication)	Meningitis, whether tuberculous, suppurative, posterior-basal, or epidemic cerebrospinal
Cerebral tumour, with or without hemorrhage into it	Disseminated sclerosis
Cerebral abscess	Caisson disease
Encephalitis lethargica	Hysteria.
Hemichorea	

Granted that a patient is suffering definitely from hemiplegia, the exact cause of the symptom has to be determined. The diagnosis is easy in a large proportion of cases.

1. —THE COMMONER CAUSES OF HEMIPLEGIA.

Hemiplegia of moderately rapid onset in a patient over fifty years is almost certainly due to *cerebral hemorrhage*, particularly when it is associated with coma of rapid but not instantaneous onset, when there is a high blood-pressure and enlargement of the heart, with a ringing aortic second sound, with or without albuminuria or other evidence of granular kidney or arteriosclerosis. If the hemiplegia has been of gradual onset in a young adult, particularly if one limb is very much more affected than the rest of that half of the body, if there had been premonitory symptoms for some hours, or even days, before the paresis became marked, and if there has been no loss of consciousness, the probability is that the patient is suffering from *syphilitic endarteritis* of the middle cerebral artery, with or without secondary *thrombosis*. The diagnosis may be confirmed by a history of syphilis, by the co-existence of leukoplakia, chronic superficial glossitis, pigmented leg-scars, cutaneous ulcers or other syphilitic lesions, or by a positive Wassermann's serum reaction.

If the patient is young, if the hemiplegia has been of absolutely sudden onset, generally without, but sometimes with, loss of consciousness, the probability of *embolism of the middle cerebral artery*, secondary to *mitral stenosis* or to *fungating endocarditis*, will be considerable, and the diagnosis will generally be confirmed by physical examination of the heart, and by inquiry into the history as regards acute rheumatism, chorea, or other rheumatic affections. The signs of fungating endocarditis are described on p. 45.

If the patient has been hemiplegic from birth or from early infancy, the probability is that there has either been *an injury* to the opposite side of the brain at birth, or *congenital malformation* of that side, or acute inflammation of it after birth—the result perhaps of *acute encephalitis*, *sinus thrombosis*, or *meningococcal meningitis* which has recovered. It is in these infantile cases that hemiathetosis is liable to be associated with the hemiplegia.

Though the above are the commonest causes of hemiplegia at the different age-periods, it is possible for them to overlap as regards age incidence: and one occasionally sees fatal cerebral hemorrhage, apparently of the senile type, in persons not much over twenty; similarly, syphilitic thrombosis of the middle cerebral artery may not occur until after fifty; fungating endocarditis followed by cerebral embolism may occur at any age, though it is commonest in young persons: the same applies to cerebrospinal meningitis. The diagnosis will be indicated, if at all, by symptoms other than the hemiplegia.

Examination of the Cerebrospinal Fluid.—In doubtful cases assistance may be derived from lumbar puncture and analyses of the cerebrospinal fluid: the following are some of the main points in which the latter may differ from the normal under various pathological conditions:—

Appearance.—Cerebrospinal fluid is normally quite clear and free from colour, so that in a test-tube it may be difficult to distinguish it from water: when there are inflammatory changes in the central nervous system, particularly acute meningitis, the fluid becomes opalescent, turbid, purulent, or even fibrinous; and, instead of being colourless, it may develop a yellow or reddish-brown colour; when coagulable protein is also present the combination has been termed the *xantho-proteic reaction*.

Specific Gravity. Its normal specific gravity is low, lying, as a rule, between 1.004 and 1.007. It may retain a normal specific gravity even in diseased conditions, for instance in cases of general paralysis of the insane; but with inflammatory changes, such as meningitis, the specific gravity is liable to increase.

Tension. Normally the fluid drops out through the lumbar-puncture needle at a rate not exceeding 60 drops per minute. If it exudes at a lower rate no definite deduction can be drawn; but if the rate of outflow is higher than one drop per second it indicates a condition of hypertension due to disease such as meningitis, cerebral tumour, hæmorrhage, or abscess.

Reaction. Cerebrospinal fluid, normal or abnormal, is always alkaline.

Cryoscopy. The normal freezing point of the cerebrospinal fluid is -0.55°C. ; in disease it may be either above or below this; generally speaking, the greater the diminution in the freezing point the more likely is acute organic disease to be present in the central nervous system.

Sugar. The amount of reducing substance in normal cerebrospinal fluid, estimated by the reduction of Fehling's solution, is approximately 1.5 parts per 1000; in diabetes mellitus this is more or less increased; what the figures are in other conditions has not yet been established fully, but there is some evidence to show that the sugar is materially decreased in cases of meningitis, tuberculous or other, and in dementia præcox.

Urea. Urea in cerebrospinal fluid amounts normally to 0.15 parts per 1000; a material increase above this figure is common only in uræmia; excess of urea in the fluid may therefore be an important point in the differential diagnosis in cases of coma.

Proteins. There is no coagulable protein in normal cerebrospinal fluid, or at most a trace of globulin; in diseased conditions, particularly those associated with inflammation within the cranium or spinal canal, albumin, more globulin than normal, and often some nucleo-protein may be present. Coagulation of the cerebrospinal fluid on boiling is always pathological.

Various chemical tests, such as the platinochloride test for choline, and the gold chloride test, have been applied to cerebrospinal fluid in attempting to differentiate one disease of the central nervous system from another, but so far there has been no degree of certainty in interpreting the results.

Cytological Examination. The normal fluid is practically free from cells, although, owing to the impossibility of avoiding slight injury to vessels by the introduction of the lumbar-puncture needle, a few red corpuscles may be found in the centrifugalized deposit, and a few leucocytes corresponding to the numbers that would be expected in the blood represented by the red cells. It is probable that cerebrospinal fluid obtained quite free from blood contamination would be free from leucocytes. Quite otherwise is it in certain diseases—not only in acute lesions, such as meningitis, but also in chronic degenerations, such as tabes dorsalis and general paralysis of the insane. The centrifugalized deposit should be examined, not merely for the presence or absence of leucocytes, but also for the different relative proportions of polymorphonuclear cells and of lymphocytes. A considerable number of polymorphonuclear cells generally indicates bacterial infection of the subarachnoid space by some organism other than the tubercle bacillus, especially streptococci, staphylococci, pneumococci, and meningococci. Some degree of polymorphonuclear excess may, however, accompany the characteristic lymphocytosis of a few cases of tuberculous meningitis. Mononuclear proliferation—lymphocytosis—indicates, as a rule, a subacute or chronic inflammatory or degenerative condition; it almost invariably accompanies syphilitic lesions of the central nervous system, particularly general paralysis and tabes dorsalis; it is also to be expected in tuberculous meningitis, and in sleeping sickness. It is not, however, pathognomonic of any of these, for it has been observed also in entirely different conditions, such as herpes zoster, acute anterior poliomyelitis, encephalitis lethargica, some cases of cerebral tumour, lymphatic leukaemia, chloroma, and even mumps. Although lymphocytosis generally indicates chronic mischief, and polymorphonuclear leucocytosis acute infection, in the later stages even of acute microbial infections mononuclear cells may be more numerous in the cerebrospinal fluid than are the polymorphonuclears. In a few cases of new growth, especially sarcoma, affecting the spinal cord or its meninges, the diagnosis has been suggested by the discovery of large atypical cells in the fluid obtained by lumbar puncture.

Bacteriological Examination.—Normal cerebrospinal fluid is sterile. In pathological conditions it may be examined bacteriologically in various ways, including direct staining of films made from the centrifugalized deposit, cultural methods, and inoculation into animals. The most important organisms that have been found are the pneumococcus, streptococcus, *Bacillus tuberculosis*, meningococcus (Weichselbaum's *Diplococcus intracellularis meningitidis*), pneumobacillus, staphylococcus, *Bacillus typhosus*, *Bacillus influenzae*, *Spirochæta pallida*, and, probably as a terminal infection only, the *Bacillus coli communis*. The cerebrospinal fluid may be used for testing for Wassermann's reaction for syphilis in the same way as is blood serum; the test is not necessarily positive in the former when it is in the latter, but when the cerebrospinal fluid itself gives a positive reaction there is almost certainly active syphilitic disease of the nervous system. It is important to know that a negative Wassermann reaction in the blood does not exclude syphilis of the nervous system—the blood is negative in not a few cases of tabes dorsalis, for example, even when no antisymphilitic remedies have been employed. The *Treponema pallidum* (*Spirochæta pallida*) has been found in the cerebrospinal fluid, but it is more likely to be detected in the local syphilitic lesions. The only protozoon at all constantly met with in the cerebrospinal fluid in disease is the *Trypanosoma gambiense* in cases in which the trypanosomiasis has reached the stage of sleeping sickness.

The Gold Curve. Lange's colloidal gold test as applied to cerebrospinal fluid promises to afford information of diagnostic importance, but experience with the test is required before one can rely upon conclusions based upon it. Colloidal gold solution is of a red colour; the addition of healthy cerebrospinal fluid free of blood admixture leaves the solution still red; in cases of tabes dorsalis, cerebral syphilis, general paralysis of the insane, tuberculous meningitis, meningococcal meningitis, suppurative meningitis, the cerebrospinal fluid changes the colour of the gold solution through a series of tints from red to blue-red, violet, blue, pale blue, to colourless. When the test is being applied, a series of tubes is prepared containing dilutions of cerebrospinal fluid of $\frac{1}{10}$, $\frac{2}{10}$, $\frac{1}{10}$, $\frac{1}{10}$, $\frac{1}{10}$, $\frac{1}{10}$, $\frac{1}{10}$, $\frac{1}{10}$; the same amount of standard colloid gold solution is added to each, the colour changes are noted, and they are then plotted out in a curve—the *gold curve*. Those who have special experience in interpreting the gold curves thus obtained are able, it seems, to decide, for instance, whether the patient has general paralysis of the insane or merely tabes dorsalis without general paralysis, and so on; but more work is required upon the subject before one can dogmatize as to the reliability of the interpretations.

B.—LESS USUAL CAUSES OF HEMIPLEGIA.

Amongst the less usual causes of hemiplegia it is worthy of particular mention that *general paralysis of the insane* sometimes attracts little or no attention until a seizure of some kind occurs, this seizure not infrequently being epileptiform, and sometimes producing a hemiplegia closely simulating that due to cerebral hæmorrhage. The diagnosis may be uncertain until the course of the case can be followed, but Wassermann's serum reaction, and the lymphocytosis in the cerebrospinal fluid, may each serve to point to the true nature of the case. Another feature is the very rapid rate of temporary recovery exhibited by some patients: deeply comatose and hemiplegic when seen upon the day of seizure, nearly all the symptoms may have disappeared by the next morning in a way that would be unusual were they due to a hæmorrhage of sufficient size to cause so deep a coma.

In elderly people, incomplete hemiplegia may occur rapidly but transiently over a period of years, in such a way as to suggest during the first attack or two that there has been an actual extravasation of blood within the brain. The rapidity with which the hemiplegic symptoms may disappear, and the way in which they may recur and yet disappear again each time, render it probable that these patients are not suffering from the effects of recurrent small hæmorrhages, but from a condition of partial occlusion of their cerebral vessels by atheroma to such an extent that, whereas the circulation is just sufficient for the needs of the brain at one time, it is just insufficient at other times; the result being that when the insufficiency of cerebral circulation is most in evidence, weakness of a hemiplegic type ensues, to disappear when rest in bed restores the cerebral circulation to a sufficiency again. *Intermittent claudication* is the name used to describe this sort of condition, but its causation is more likely due to *borderland sufficiency of circulation* than to vagaries in the vasomotor control of the vessels.

Cerebral tumour or cerebral abscess may produce hemiplegia by infiltrating either the cerebral cortex or the pyramidal tract directly, or by these becoming involved in the softening around the tumour or the abscess : in most cases there will be a history of weeks or months of headache, giddiness, and effortless vomiting, with or without signs of irritation previous to the paralysis ; optic neuritis of the choked disc type (*Fig. 418*, p. 518) may be found with the ophthalmoscope, and in the abscess cases there will generally be a predisposing cause, such as otitis media. A tumour or an abscess within the cranium may be latent for months, however, and in some such cases symptoms may come on acutely, especially if there has been hæmorrhage into a softening tumour. Ordinary cerebral hæmorrhage may be simulated in this way, but if well-marked optic neuritis is found in both eyes, the cause is probably not hæmorrhage only. The existence of pyrexia is not by itself evidence of abscess, for hæmorrhage near the internal capsule, or in the motor cortex, often leads to some rise of temperature for the time being, whilst pontine hæmorrhage is not infrequently associated with hyperpyrexia, and in not a few cases of intracranial abscess pyrexia is conspicuously absent.

Injury to the spinal cord in the cervical region is a rare cause of paralysis of the arm and leg upon the same side : first, because trauma here is liable to damage more than half the cord ; and, secondly, because the injury must involve the lower part of the cervical enlargement if the arm is to be paralysed, and it is, therefore, very liable to interfere with the subsidiary respiratory centres, and thus prove rapidly fatal. Occasionally, however, either a knife stab or a bullet wound on one side of the neck produces hemiplegia with evidence of unilateral paralysis of the diaphragm, as observed when the patient's abdominal respiratory movements are watched in a good light. It has sometimes been asserted that the patient will have anaesthesia, not of the same, but of the opposite side of the body : in practice this is not generally the case, the hemiplegia and the hemi-anaesthesia being on the same side as the lesion in at least some instances.

Children of a rheumatic tendency who are subject to *chorea* sometimes present the movements of the latter upon one side of the body only : *hemichorea* ; both before the actual movements appear and after they have ceased there is apt to be considerable, and occasionally extreme, weakness of the affected side ; so much so that some intracranial lesion may be suspected, unless there has been clear evidence of the existence of chorea.

Occasionally, weakness of a hemiplegic nature may be the first symptom of *meningitis*, whether tuberculous, suppurative, posterior basal, or epidemic cerebrospinal ; sometimes, upon post-mortem examination a definite unilateral softening, or a tuberculous nodule affecting the pyramidal fibres, may be found to account for this ; but more often the appearances seen after death fail to explain why there should have been unilateral parietic symptoms. In the earlier stages the diagnosis may be quite obscure, but sooner or later the paresis becomes bilateral, and the course of the disease indicates meningitis beyond doubt, especially if there are convulsions, vomiting, and optic neuritis. Choroidal tubercles may be detected in some cases (*Fig. 429*, p. 520) ; cytological and bacteriological examination of the cerebrospinal fluid may assist in arriving at the diagnosis.

Disseminated sclerosis is a very slowly progressive disease in which during the earlier stages the foci of sclerosis are few and irregularly distributed, so that whereas in the later stages ataxy, intention tremor, more or less spasticity with increased knee-jerks, extensor plantar reflexes, ankle-clonus, and either slurred or staccato speech, are to be expected, these are only present when, in the course of years, numbers of sclerotic foci have accumulated in the spinal cord and brain ; long previous to this there have been irregular symptoms, amongst which may be hemiplegia ; the diagnosis at this stage is often a matter of opinion only, though if the patient can be watched over a sufficient length of time the nature of the case ultimately becomes obvious.

The symptoms of *caisson disease* are due to the liberation of air-bubbles in the nervous system, and what the symptoms will be depends on where these bubbles are ; in most instances they are widely scattered, so that bilateral paralyses are more common than unilateral ; it is possible, however, for caisson disease to produce hemiplegia if a relatively large air-bubble becomes liberated in or near the internal capsule. The diagnosis depends on the history and occupation.

Hysteria may be responsible for almost any form of nerve symptom, hemiplegia being a not uncommon variety. There is no wasting, except that which may be due to disuse ;

the knee-jerks may be exaggerated, but the plantar reflexes will remain flexor, and there is no ankle-clonus : the face, as a rule, is unaffected : if the patient, lying flat upon her back, is asked to raise her legs from the bed, she will raise the sound leg, but not that which is paretic : whereas, in a case in which there is incomplete paralysis of one leg due to organic lesions of the upper neuron upon one side, an attempt to raise the leg in this way often leads to the paretic leg being lifted as well as the other. The sex and age of the patient, her previous history, and possibly the presence of other functional nerve symptoms (p. 570), would indicate the diagnosis.

Herbert French.

HICCOUGH is a symptom which more often than not has no clinical significance, resulting, as it does even in the healthiest people, from excessive laughter, from stimulation of certain reflex spots, especially about the chin, from tickling, or even coming on spontaneously without any obvious cause at all.

Alcoholism.—The hiccough of this condition has a character of its own, and the circumstances will indicate the diagnosis.

Peritonitic Hiccough is of bad omen, but it seldom helps in diagnosis, for the patient who has an acute abdominal condition associated with hiccough will have presented grave symptoms before hiccough sets in, the diagnosis often having been arrived at by urgent laparotomy. The hiccough in these cases does not serve to distinguish between acute peritonitis due to whatever cause, acute hemorrhagic pancreatitis, acute intestinal obstruction from any cause, or acute post-operative dilatation of the stomach ; its occurrence and persistence, however, indicate a grave prognosis.

When persistent or recurrent hiccough is a troublesome symptom in a patient who is not otherwise extremely ill—so troublesome that something more than a simple hiccough has to be thought of—the main types of malady that will suggest themselves are the following :—

Hysteria or neurosis	Certain chronic abdominal lesions
Mediastinal irritation of vagi or phrenic nerves, e.g., by caseous glands	Uranic hiccough
Tabes dorsalis with hiccough crises	Chronic degenerative changes in the medulla oblongata.
Acute epidemic hiccough	

Functional Hiccough is a remarkable malady hardly to be mistaken. The patient is generally a girl between 15 and 25 years of age, and she may hiccough persistently throughout her waking hours for weeks, at the rate of two or three times a minute. She will sleep well, and the hiccough stops during sleep. She will eat well, but may hiccough during meals in a most distressing way. She will have exaggerated knee-jerks, brisk flexor plantar reflexes, and she will be amenable to treatment by suggestion. Whether treated or not, the hiccough will cease in time ; often it will be noticed to have come in the place of some other neurosis (p. 570), and when it goes it may be replaced by other functional nerve symptoms. The chief difficulty will probably be to exclude the case of a sporadic example of epidemic hiccough (see below).

Irritation of a Vagus or Phrenic Nerve by something in the mediastinum causes current attacks of intractable hiccough only in rare cases. In a child, the least uncommon cause is *tuberculous caseation of bronchial and mediastinal glands* ; these seldom obstruct a bronchus or in other mechanical ways afford evidence of their presence ; but they may be associated with periodic attacks of febrile illness in a patient who looks delicate, and who has been in the habit of drinking much milk ; and there may be evidence of chronic enlargement of the glands elsewhere, particularly those in the neck or in the abdomen. It may be possible to see the shadow of the gland with the X rays (*Fig. 155*, p. 187). *Adherent pericardium*, or any cause of great *enlargement of the heart*, may also produce hiccough. In an adult the least uncommon causes are either *malignant* or *lymphadenomatous deposits* in the mediastinum, or else *fibrous mediastinitis*. The former may be indicated by reason of there being symptoms of a primary growth in the œsophagus or elsewhere, or by progressive varicosity of the veins of the chest wall, or signs of recent and increasing obstruction to a bronchus : chronic mediastinitis has generally been preceded by repeated attacks of pleurisy and pericarditis, especially in those subject to acute rheumatism. Hiccough is an exceptional symptom in these cases.

Tabes Dorsalis is not a common cause of persistent hiccough ; but now and then

one meets with a case in which bouts of hiccough seem to take the place of other tabetic crises—*hiccough crises* as it were—and the paroxysms may be distressing, prolonged, and intractable to treatment. The diagnosis is indicated by the absence of tendo-Achillis jerks, the absence of knee-jerks, and by the Argyll-Robertson pupils.

Epidemic Hiccough is of uncertain nature, but, rare though it is, it is of extreme importance in that it is fatal in a certain proportion of cases, and yet may be mistaken at first for a neurosis. The diagnosis is only easy when there is an epidemic in the district: the patient hiccoughs continuously, or with but transient remissions, for days and nights in spite of all sorts of treatment; the illness may subside spontaneously within a week, or the patient may die and present little if any post-mortem evidence of what has killed him. There is a belief that the malady is closely allied to encephalitis lethargica, the inflammatory processes affecting centres in the medulla instead of those in the mid-brain; if there are ocular paresis and other symptoms of mid-brain inflammation at the same time the diagnosis is less difficult; or the condition may be suspected if the patient is febrile: sometimes, however, there is no pyrexia, nothing abnormal in the cerebrospinal fluid on lumbar puncture, and little if anything to distinguish this serious form of hiccough from that due to hysteria or neurosis, unless it happens that there have been other similar cases in the neighbourhood about the same time.

Abdominal Disease.—A few patients suffering from serious but not urgent abdominal disease develop distressing hiccough in some reflex way that is not understood; in a few instances it may be that the diaphragm is being irritated, for example by *subphrenic abscess*, *subdiaphragmatic peritonitis*, secondary deposits of *cancer in the liver*, a *gumma* or *abscess in the liver*, an *infarct in the spleen*, or a *carcinoma of the stomach*; but sometimes the mischief seems far removed from the diaphragm—a *carcinoma of the sigmoid colon*, for instance, or *cancer of the womb*, even when there are no secondary deposits.

Uræmic Hiccough is rare, but it may be persistent and of grave omen; the diagnosis will depend on the associated evidence of renal disease—whether this be of Bright's disease type, or the result of stricture, enlarged prostate, coli bacilluria, cystitis, or other infective trouble in the urinary passages.

Degeneration of the Medullary Centres.—If hiccough is due to this cause it will almost certainly be associated with other symptoms of cerebral or spinal mischief; in a young adult there might be a suggestive history of syphilis or chronic alcoholism, whilst in an older person there would be thickened and tortuous arteries, a high blood-pressure, an enlarged heart, areus senilis, albuminuria—signs of senile degeneration. *Herbert French.*

HIPPUS. (See PUPIL ABNORMALITIES OF THE, p. 674.)

HOARSENESS. Hoarseness may be slight or severe, transient, recurrent, permanent, according to the nature of its cause; the following list includes some of the conditions to which it may be due:

Overuse of the Normal Vocal Cords:

1. Habitual: Clergymen; Stockbrokers; Costermongers; Bookmakers.
2. Occasional: Shouting at a football match, etc.

General Weakness, so that even Slight Use of the Voice Tires the Cords:—

Convalescence	Myasthenia gravis	Acromegaly
Severe debility	Myxœdema	Graves' disease.
Severe anaemia		

Microbic Infection of the Larynx, short of Ulceration:

Congestion	Measles
Acute laryngitis	Chronic laryngitis
Diphtheria	Syphilitic laryngitis + pre-ulcerous
Variola	Tuberculous laryngitis + stages.

Chronic Laryngitis Due to Causes other than Obvious Microbes:—

Alcoholism	Gout	Tobacco smoking.
------------	------	------------------

Foreign Body in the Larynx:—

Breaderumb	Food gone the wrong way	Acrid gastric contents re-
Fly		gurgitated in pyrosis.

Gases affecting the Larynx :—

Chlorine	Ammonia	London fog, etc.
Steam	Mustard gas	

Spasm of the Laryngeal Muscles :—

Croup	Tetanus	Laryngeal crises of tabes dorsalis.
Tetany	Strychnine poisoning	

Paralysis of Vocal Cord :—

Aortic aneurysm	Malignant cervical lymphatic glands	Injury to recurrent laryngeal nerve during thyroidectomy.
Mediastinal new growth	Epithelioma of œsophagus	
Thyroid gland tumour		

Crico-arytenoid Lesions :—

Perichondritis of the cricoid cartilage	Perichondritis of the arytenoid cartilage	Ankylosis of the crico-arytenoid joint.
---	---	---

Fibrositis of any of the Laryngeal Muscles.**Ulceration of the Larynx :—**

Tuberculous	Epitheliomatous	Lupus
Syphilitic	Leprous	Traumatic.

New Growth of the Vocal Cord : Sessile wart ; Papilloma ; Angioma ; Epithelioma.**Displacement or Compression of the Larynx producing Deformity :**

Retropharyngeal abscess	Huge thyroid-gland enlargement	Malignant disease in neck.
Cervical caries		Actinomycosis of the neck.
Epithelioma of the pharynx	Malignant disease in floor of mouth	

Œdema of the Larynx :—

Irritant gases	Bright's disease	Aspirin
Laryngitis, of any kind	Angioneurotic œdema	Iodide of potassium.

In arriving at a diagnosis of the cause of hoarseness in any particular case the history carries one far, particularly in regard to how rapidly the symptom developed, how long it has been present, whether it is now improving, and whether it is associated with sore throat or other evidence of local catarrh. Perhaps it would always be wise to examine with the laryngoscope, but in the majority of cases this is not essential, for the condition clears up under simple treatment. When, however, there is anything about the clinical state that leaves a doubt as to the actual condition of the vocal cords, aryteno-epiglottidean folds, cricoid cartilage, arytenoid cartilage, or neighbouring parts, it becomes essential to inspect the parts with the aid of the laryngoscope, and it may require the experience of a specialist in this department to interpret correctly what is seen. The chief points that call for answer are :

My patient is no longer young and he has complained of a troublesome hoarseness times for the last few weeks ; can I be sure that he is not developing an epithelioma of a vocal cord ?

My patient was suspected of having phthisis a year or two ago, but has been regarded as cured ; now he gets slight but definite hoarseness from time to time : is this due to simple catarrh only, or is there evidence of incipient tuberculous laryngitis ?

My patient has had a curious huskiness of his voice during the last six months ; is there any vocal-cord paralysis ?

My patient has a husky voice at times and I can see a swelling on one vocal cord ; is this malignant, or is it only a wart or a papilloma ?

It is from the laryngological appearances that the diagnosis is made ; and *Figs. 209-212, p. 245*, indicate some of the things that may be seen. New growths, whether benign or malignant, are nearly always unilateral ; tubercle, syphilis, catarrhal laryngitis, bilateral. Distinction between papilloma and epithelioma may necessitate histological examination of parts removed surgically. Syphilitic ulcers are grosser than are those of tubercle, fewer in number, and associated with evidence of fibrotic healing about them. Tuberculous ulcers are multiple, small, shallow, and they are generally seen more readily along the edge

of the epiglottis and on the aryteno-epiglottidean folds than they are on the vocal cords themselves, though in the late stages the outlines of the edges of the latter may be as much 'mouse-rubbed' as in the epiglottis, or the cords alone may be involved; previous to actual ulceration it may be possible to detect submucous tubercles in some part of the larynx; or there may be a suggestive pallid oedema of the aryteno-epiglottidean folds without any recognizable tubercles or ulcers at all. Few but specialists can be accurate in distinguishing the important from the unimportant laryngeal states, and it is upon them that one must rely in deciding between tubercle and catarrh, papilloma and epithelioma, and other laryngeal causes for hoarseness. If one were to stress one point more than another, it would be to urge early laryngeal examination in any patient of middle age who begins to be in the least hoarse without apparent cause, for hoarseness of apparently minor importance may be the only symptom produced by epithelioma of a vocal cord; the condition is painless and not associated with ill health; it is missed if it is not looked for deliberately.

Herbert French.

HYPERACUSIS, or undue sensitiveness to ordinary noises or sounds, is seldom a symptom pointing to disease of the ear itself; aural lesions such as otitis media nearly always cause impaired hearing or actual DEAFNESS (p. 205), and not hyperacusis. The latter is complained of rather by those whose brain centres are in an unstable, irritable, over-strained, or excitable state as the result of either local or general conditions which include the following:

1. Local Causes:

a. With gross lesions of the brain itself:

Tuberculous meningitis	Early stages	Gumma of the brain
Meningococcal meningitis		Abscess of the brain
Suppurative meningitis		Tumour of the brain.
Pachymeningitis		

b. Without gross lesions of the brain itself, but affecting the latter reflexly from the severity of local pain:

Tie douloureux	Severe headache from any cause
Glaucoma	(p. 369), especially sick headache
Iritis	or migraine.
Inflammatory conditions of the scalp	

c. After injury to the head—concussion.

2. General Causes:

a. During convalescence from any severe illness, especially fevers.

<i>b. Strychnine poisoning</i>	Secondary syphilis	Hysteria
Tetanus	High blood-pressure conditions	Hypochondriasis
Malaria	Neurasthenia	Graves' disease.

The circumstances of the case will nearly always indicate the nature of the cause. Probably the most marked instances of hyperacusis are met with in association with tie douloureux: it is not so much perhaps that the patient hears more acutely than usual, as that she dreads the onset of a paroxysm of facial pain which may be brought on suddenly and acutely by almost anything, often by hearing a door bang, or somebody talking loudly; she therefore complains of the least noise, and keeps herself shut up in her room, from which sounds are excluded by all kinds of special devices.

The neurasthenic patient who suffers from hyperacusis is to be pitied greatly: for, though suffering from no serious organic disease, he dreads all sounds so much that he becomes an almost useless member of society, a misery to himself and his friends. His functional sufferings may be so bad as to drive him to desperation and to suicide.

The desire for perfectly silent surroundings during an attack of sick headache or of migraine is familiar to all. The remaining affections in the list above need not be discussed in detail here, for they will be associated with other symptoms that will point to the differential diagnosis. CONVULSIONS (p. 180) for example; or EYE, ACUTE INFLAMMATION OF (p. 285), or VOMITING (p. 927), and so on. One would add, however, that before

diagnosing a case as purely functional, the blood-pressure should be measured instrumentally, and the urine tested for albumin, in case the cause is arteriosclerosis or chronic nephritis with hyperpiesis : and in not a few cases it is advisable to have the blood tested for Wassermann's reaction, for it is noteworthy that unsuspected syphilis may be the cause of various obscure nerve symptoms that at first sight appear purely functional. *Herbert French.*

HYPERIDROSIS. (See SWEATING, ABNORMALITIES OF, p. 803.)

HYPERPYREXIA. The point at which pyrexia becomes hyperpyrexia is arbitrary : by some it is fixed at 105° F., by others at 106° F. It may occur occasionally in many different diseases, but it is seldom itself of diagnostic significance. The patient will nearly always have exhibited other symptoms or signs pointing to the diagnosis : therefore the following list of maladies in which hyperpyrexia may occur needs little discussion :

1. Fevers of Microbial, or probably of Microbial, Origin :—

Lobar pneumonia	Malignant endocarditis	Cholera
Bronchopneumonia	General tuberculosis	Dysentery
Scarlatina	Tuberculous meningitis	Yellow fever
Pyæmia	Posterior basal meningitis	Rheumatic fever
Septicæmia	Epidemic cerebrospinal meningitis	Chorea insaniens
Erysipelas	Suppurative meningitis	Uremia due to ascending nephritis
Typhoid fever	Malaria	Pyelitis.
Typhus fever	Relapsing fever	
Tetanus		

2. Lesions of the Central Nervous System :—

Cerebral hæmorrhage, especially pontine, or into one optic thalamus	Cerebral tumour or abscess, especially tumour of the pons Varoli
Fractured skull, with confusion of the brain	Fractured spine, especially in the lower cervical or upper dorsal regions
Cerebral softening	Acute myelitis after injury.

3. Affections that are less easy to classify :—

After burns or scalds	Uremia other than that due to septic nephritis
Heat-stroke or sunstroke	Acute yellow atrophy of the liver.
Infantile convulsions	
Delirium tremens	

4. Hysteria.

There are, however, certain small points about hyperpyrexia that may be important in diagnosis.

Acute rheumatism is sometimes stated to be a prominent cause of it : as a matter of fact hyperpyrexia is excessively rare in acute rheumatism, so that if it occurs in a case that has been regarded as rheumatic fever the diagnosis should be carefully revised lest it be septicæmia.

In children the physical signs alone may leave one in doubt as to whether there is bronchitis only, or bronchopneumonia, or even general tuberculosis of the lungs : the occurrence of hyperpyrexia generally indicates that there is more than bronchitis : if the patient is not particularly livid, bronchopneumonia is more likely than general tuberculosis : the latter becomes the more probable the more ill the patient is out of proportion to the physical signs. Occasionally hyperpyrexia occurs in an infant or child after a fit, without any definite cause being assignable either for the convulsion or for the high temperature, and without any serious consequence resulting.

In tuberculous meningitis hyperpyrexia is generally terminal : in *posterior-basal meningitis*, on the other hand, it sometimes occurs periodically and transiently, producing acute upward 'spikes' upon a temperature curve that is not otherwise very high : these pyrexial 'crises' (*Fig.* 578, p. 733), as they have been called, point to posterior-basal or meningococcal rather than to the more serious tuberculous meningitis.

Hyperpyrexia may sometimes serve as the chief point in distinguishing *pontine hæmorrhage* or *heat-stroke* from other forms of coma, such as acute alcoholism or opium poisoning : in the latter the temperature is below normal. The circumstances of the case, such as climatic conditions or occupation, will generally serve to distinguish between heat-stroke

and pontine haemorrhage, and the latter is the more probable if there is a bilateral extensor plantar reflex.

After an injury to the back—for instance, by a fall in the hunting field—the occurrence of hyperpyrexia sometimes serves to exclude the diagnosis of a mere bruising, and to point to the gravity of the condition—a fractured or dislocated spine near the cervical region, or acute traumatic myelitis or softening of the upper part of the spinal cord.

The diagnosis of the other diseases mentioned in the above list is not much assisted by the occurrence of hyperpyrexia.

It only remains to add a word or two about *hysteria* and high temperatures. There can be no doubt that, in exceptional cases, nearly all of which are of the female sex, the mercury in the clinical thermometer does actually rise to a very high figure without there being any corresponding illness in the patient. Malingeringers have sometimes learned a trick, such as compressing the bulb of the thermometer enough to send the mercury up, or deliberately heating the thermometer in a cup of tea or against a hot-water bottle; but quite apart from malingering, it would seem that there are females in whom, for some reason, the mercury really does record temperatures that are not those of the internal tissues. Readings have been taken simultaneously in the mouth, armpits, and rectum, all possibility of malingering being excluded by special precautions: all the thermometers registered hyperpyrexia. The diagnosis is generally made by the fact that the readings are so high that they must be unreal: the following have been recorded in various cases: 107°, 108°, 111°, 113°, 115·8°, and even 116·4° F. In most of these patients the symptoms were slight, though sometimes there have been flushings, headache, restlessness, and various functional nerve symptoms, or even delirium and convulsions. Unless it is at once obvious that the patient is not really ill there must always be difficulty, danger, and anxiety in arriving correctly at the diagnosis of hysterical hyperpyrexia: the nature of the case may remain in doubt until the course and result have been watched, and it will sometimes tax the physician's ingenuity to detect malingering as the alternative to hysterical hyperpyrexia.

Herbert French.

HYPERTROPHY OF THE HEART. (See ENLARGEMENT OF THE HEART, p. 257.)

HYPOCHONDRIUM, PAIN IN. (See PAIN IN THE HYPOCHONDIUM, p. 553.)

HYPOTHERMIA signifies a condition of subnormal temperature, and generally speaking it is assumed to refer to the temperatures registered by the thermometer in the mouth. Rectal temperatures do not coincide with those of the mouth: the greater part of clinical thermometry is based on mouth or axillary or groin temperatures, and the clinical significance of variations in rectal temperatures is familiar to a relative minority of medical men. From a diagnostic point of view hypothermia is not often a symptom of great importance, but there are at least two points about it that require special mention. In the first place, coma due to *opium poisoning* may be closely simulated by coma due to *pontine haemorrhage*: in both there are bilateral loss of movement, pin-point pupils, and few other symptoms: with opium poisoning, however, the temperature becomes sub-

Fig. 314. Temperature chart, mouth, over 28 hours, illustrating hypothermia in connection with chronic valvular disease. There was an independent attack of nonfatal on the thirteenth day, which raised the temperature to 98·6°, which was the only reason for the patient's, whose normal mouth temperature was between 98° and 98·4°.

normal, whilst with pontine haemorrhage it tends to rise to the level of hyperpyrexia, so that the thermometer may be the means of diagnosing between them. In the second, patients suffering from *chronic valvular heart disease*, with symptoms of impending or actual failure of compensation, very commonly suffer from hypothermia. This is a point not always emphasized sufficiently: not a few cases of heart disease have for their normal temperature base-line not 98·4° F., but 97° F., or even 96° F. (Fig. 314). It follows that a patient whose normal temperature is 96° F., really has over two degrees of fever when his temperature reaches 98·4° F.: he may develop fungating endocarditis on the top of his chronic valve lesion, and yet his temperature may not rise materially above 98·4° F. The fact, therefore, that hypothermia is a common feature in heart cases has

great importance, for it indicates the necessity for regarding even slight rises above 98.4° F. with greater seriousness in them than in other cases.

For the rest it will suffice to indicate the chief causes of hypothermia, which are as follows :

Chronic Debilitating Maladies, such as :

Chronic valvular
heart disease
Addison's disease
Diabetes mellitus

Cretinism
Arteriosclerosis
Myxœdema

Chronic nephritis, with or
without uræmia
Inanition, malignant or
otherwise (*Fig. 315*).

Coma due to poisons, particularly :

Opium
Alcohol

Chloral
Anæsthetics

Carbolic acid
Oxalic acid.

Increased Intracranial Pressure in certain cases of :

Cerebral abscess
Cerebral tumour

Cerebellar abscess
Cerebellar tumour

Cerebral hæmorrhage.

These same lesions, especially if they involve either the pontine or the subthalamie regions, or if they affect the corpus striatum, may produce pyrexia or even **HYPERPYREXIA** (p. 390) instead of hypothermia, so that the inconstancy of the latter symptom detracts considerably from its value in differential diagnosis in these cases.

Convalescence after certain fevers : for instance :

Pneumonia

Typhoid fever

Relapsing fever.

Shock after **severe injury** or after a **serious operation**.

Collapse due to loss of fluid from the tissues from such conditions as :

Severe vomiting,
whatever the cause

Severe diarrhœa, choleraic or
otherwise
Peritonitis

Intestinal obstruction
Hæmorrhage.

Exposure, especially in the case of a child, or after *immersion*.

In the morning, in cases of Intermittent Pyrexias of the septic or hectic types. It is important that the temperature should have been taken both night and morning

before the low figures for the morning are assumed to indicate continued hypothermia : very low readings in the earlier part of the day in a patient whose malady is not at once obvious may arouse suspicion of a tuberculous lesion which further investigation may confirm.

Fig. 315. Temperature chart illustrating hypothermia in a child, from inanition. The patient, a man of 44, had a tuberculous infection with a collection into the left pleural cavity.

It is a point of clinical interest that, although the human normal temperature is upon the whole remarkably constant all over the world, *Anglo-Indians* and those who have resided long in the Tropics are frequently found to have persistently low normal mouth temperatures when they return to England on retirement ; thus it is quite common for them to have a normal temperature as low as 96° F., or in a few instances even 94° F.

Herbert French.

ICTERUS. (See JAUNDICE, p. 405.)

ILIAC FOSSA, PAIN IN. (See PAIN IN THE ILIAC FOSSA, p. 555.)

ILIAC FOSSA, SWELLING IN. (See SWELLING IN THE ILIAC FOSSA, p. 826.)

IMPOTENCE, strictly speaking, includes any condition, whether in the male or in the female, that prevents the performance of coitus ; it has come to be restricted to inability on the part of the male. It is not synonymous with sterility ; the latter, in the

male, implies absence of the living spermatozoa necessary to fecundation: a man may be sterile without being impotent, or impotent without being sterile, or both impotent and sterile. There are three main groups of conditions which lead to impotence, namely:—

1. **Mechanical Defect**, such as congenital or acquired malformation of the penis, absence of the penis, carcinoma, elephantiasis, and so on. These need not detain us, for the diagnosis is generally obvious on inspection: one need only say that even considerable deformities of the genital organs are by no means necessarily associated with impotence.

2. **Entire Absence of Penile Erections**, as the result either of some organic disease of the nervous system, or of some general constitutional condition: one may mention particularly the following:

Tabes dorsalis	Diabetes mellitus	Alcoholism
Ataxic paraplegia	Atrophy of the testicles from injury or from severe orchitis, gonorrheal or otherwise	X-ray effects
General paralysis of the insane		Neurasthemia
Primary spastic paraplegia		Excessive masturbation
Disseminated sclerosis	Senility	Pernicious anemia
Anyotrophic lateral sclerosis	Congenital frigidity	Malarial cachexia
Transverse softening of the cord	Infantilism	Syphilitic cachexia
Plumbism	Hypopituitarism	Cancerous cachexia
Compression of the lower part of the cord	Morphine habit	Phthisical cachexia
Dementia	Heroin habit	Exhaustion from excesses.
	Cocaine habit	
	Paraldehyde habit	

There is little need to discuss these further here, for, providing they are borne in mind, they will be diagnosed readily as the result of a careful routine examination of the nervous system, urine, lungs, and so on. One need only add that impotence may be an early symptom in ataxic paraplegia, disseminated sclerosis, and phthisis, and that the diagnosis may seem to be neurasthenia only until the case has been watched.

3. **Fetishism** merits special mention in that, although the man may be impotent under what might be termed ordinary or usual circumstances, he is able to perform the sexual act under unusual or special conditions. For instance, he may be impotent in his own house, but thoroughly competent at an hotel: he may be impotent in bed, but not upon the hearth-rug in the firelight: he may be unable to have coitus if his wife has her legs bare, but may be sexually strong if she wears silk stockings at the time: this condition of affairs is a psychoneurosis, the man being impotent unless there are special and unusual circumstances attending the act, and to this state of affairs the name *fetishism* is given.

4. **Impotence due to Inability to obtain Erections at the right time**. This is a very common form of the symptom: the patients are generally told they are suffering from neurasthenia; and so they are, of a particular sort. This is another form of psychical or nervous impotence: strong erections may be present at inopportune times, there may be emissions during sleep, and yet at the very moment when sexual intercourse is intended the erection is either quite absent or imperfect. Sometimes, owing to extreme irritability, emission occurs on so little excitation that it takes place before insertion is complete, the rigidity of the penis relaxing almost at once, so that completion of coitus becomes impossible. Temporary impotence of this kind is not at all uncommon during the first few days or weeks of married life, especially if the wedding has been preceded immediately by particularly hard business strain or mental overwork preparatory to the honeymoon. The diagnosis is arrived at partly by the history, partly by the negative result of careful physical examination of all the systems, especially the nervous and pulmonary: but the final criterion is the effect of time. Where there is no organic cause for the symptom normal coitus will occur presently if the patient ceases to be over-anxious about it.

Herbert French.

IMPULSE, DISPLACED CARDIAC. (See HEART IMPULSE, DISPLACED, p. 372.)

INCONTINENCE OF FÆCES. Evacuation of the contents of the rectum without voluntary control or initiation may occur under varied conditions, and the symptom is of importance chiefly when it is associated with other evidence of gross disease of the central nervous system.

In healthy persons the reflex relaxation of the sphincter ani which is necessary for defecation takes place only at the bidding of the will. Some healthy persons are better able to resist an imperative call to stool than others: it happens occasionally that an individual who is poorly endowed with the power of inhibiting the reflex may suffer from an incontinence of feces when the stimulus evoked by irritating contents of the bowel is overpoweringly strong, and this even when there is no disease to account for it. The individual would be conscious of the accident, which would be of rare occurrence, and examination would reveal no abnormality. Children often suffer in this way. Somewhat similar 'explosive diarrhoea' is also a prominent feature of certain cases of carcinomatous stricture of the sigmoid or pelvic colon, or of the rectum.

Mechanical incontinence of feces results from injuries or diseases of the rectum or perineum, such as carcinoma, in which the outlet of the bowel is no longer guarded by an efficient sphincter, or extensive damage to the musculature such as may result from perineal tears after childbirth, or after operations for fistula, fissure, or piles, when the sphincter ani may have been overstretched or divided. Local inspection and digital examination of the parts will suffice to discover the cause of such incontinence.

In conditions of coma or partial unconsciousness, from whatever cause arising, reflex emptying of the bowel may occur at intervals, particularly if aperients are administered. Digital examination of the rectum in such cases will reveal a normal sphincter which closes on the observer's finger.

Injuries or diseases of the central nervous system above the sacral region of the cord, if they interfere with impulses passing from the cortex to the lumbosacral enlargement but do not cause serious sensory disturbance in the perineal area, lead to an unstable condition to which the term 'precipitancy of defecation' is applied. In these circumstances the patient is usually constipated, but the call to stool, when it comes, spontaneously or as the result of aperient medicine, is imperative, and finds the patient powerless to resist or delay the act. The examination of such a person discloses a normal sphincter but, in all probability, some degree of spastic paraplegia, with brisk tendon jerks and extensor plantar responses, and inquiry will elicit the history of precipitate micturition. Moreover, the patient will be conscious of the acts of defecation and micturition. This association of signs and symptoms is common enough in cases of partial injury to the spinal cord, in cases of old dorsal myelitis, of disseminated sclerosis, of syringomyelia, of tabes dorsalis, etc.

With more serious disease of the central nervous system above the sacral region, the impulses conveying the need for defecation do not reach the brain, and the act takes place in a reflex manner without the knowledge of the patient. Under these circumstances, paraplegia with sensory disturbance over the sacral segmental areas will help to localize the site of the lesion. The tone of the sphincter ani may be little below normal or quite unimpaired.

Disease or injury leading to destruction of the sacral cord or of the cauda equina is illustrated by the fact that incontinence of feces is associated with an *insensitive relaxed sphincter* and with serious motor, sensory, trophic, and reflex disturbances in the lower extremities. When the feces are small and fluid they escape, more or less continuously, through the gaping anal aperture. On the other hand, they sometimes tend to accumulate in dry masses too large to pass the portal without assistance. The patient is unconscious of the accumulation, unconscious of soiling, and insensitive to the exploring finger.

It will be understood from the above statements that for the purpose of diagnosis it is necessary, in all cases of fecal incontinence, not only to inquire into the exact features of the incontinence, the presence or absence of a call to stool, the tendency to constipation or precipitancy, the ability to feel the passage of motions, etc., but to supplement the knowledge gained in this way by a local examination, especially of the sphincter ani, and an investigation of the motor, sensory, and reflex conditions in the lower extremities.

E. Farquhar Buzzard.

INCONTINENCE OF URINE. (See ENURESIS, p. 270; and MICTURITION, ABNORMALITIES OF, p. 490.)

INCO-ORDINATION.—(See ATAXY, p. 73; and GAIT, ABNORMALITIES OF, p. 313.)

INDICANURIA. Indican in the urine is mainly due to the formation of indol in the intestine as the result of putrefactive changes in the products of tryptic digestion of proteins. The indol so formed is absorbed from the bowel and converted in the liver into relatively innocuous potassium indoxyl sulphate, or indican. This is tested for by oxidizing it to indigo, the blue colour of which is characteristic. Almost any oxidizing agent could be utilized for the test, but the difficulty is that even slight excess of the reagent destroys the indigo. A brown ring appearing at the junction of the urine and the acid when testing for albumin with nitric acid that is slightly fuming indicates indicanuria. To be certain of this, Jaffe's bleaching-powder test is employed. To about 20 c.c. of urine add 3 c.c. of chloroform and 3 c.c. of hydrochloric acid of medium strength: the colourless chloroform sinks to the bottom of the mixture: a drop of freshly-made calcium hypochlorite solution is now added and the test-tube inverted deliberately once or twice: a second drop is added, and so on, the colour of the chloroform being watched the while. If indican is present, it becomes oxidized to indigo, which is dissolved out by the chloroform so that the latter changes from colourless to blue, and the depth of indigo-blue colour in the chloroform affords a rough measure of the amount of indican in the urine (*Fig. 316*). The main precaution to be taken is not to add the hypochlorite solution too rapidly, for excess of it discharges the colour.

Fig. 316. Test-tube showing blue color of chloroform layer in indicanuria.

Indican being an ethereal sulphate, it is present in excess under the same circumstances as an excess of ethereal sulphates. At one time it was thought that much useful clinical information as to the condition of the intestines could be learned from its occurrence. It is true that any circumstances that are likely to increase the putrefactive changes in the protein in the bowel are also likely to increase the amount of indican in the urine, so that marked indicanuria is generally found in cases of chronic constipation, intestinal obstruction, diarrhoea, typhoid fever, dilated stomach, peritonitis, acute enteritis or colitis, appendicitis, membranous, tuberculous, or ulcerative colitis, acute and chronic dysentery, cholera, intussusception, and carcinoma coli. It affords no assistance in diagnosing between one and another of these various affections, however. Moreover, it may occur when there is decomposition of albumin elsewhere in the body than in the bowel: for instance, in gangrene of the lung, gangrenous empyema, putrid bronchitis, bronchiectasis, or advanced pulmonary tuberculosis. Another difficulty is that a considerable number of perfectly healthy individuals pass quite large quantities of indican in their urine. There are some who contend that even these healthy persons are really suffering from intestinal putrefactive changes without knowing it: this is possible, but from the patient's point of view it is tantamount to saying—what is indeed almost true—that indicanuria has no real diagnostic or clinical significance.

Herbert French.

INDIGESTION. 'Indigestion' is a symptom, not a disease: and if a patient complains of it one should inquire more particularly as to the exact nature of the abnormal sensations present, e.g., pain, fullness, flatulence, vomiting, etc. The diagnostic indications furnished by each of these symptoms is considered separately (see **VOMITING**, p. 927; **PAIN IN THE EPIGASTRIUM**, p. 536; **FULLNESS, SENSE OF**, p. 306; **FLATULENCE**, p. 302, etc.), but it may be convenient here to offer some general guidance as to the methods of arriving at a diagnosis in cases in which 'indigestion' in one or other of its aspects is the chief complaint.

I. SIMULATION OF DYSPEPSIA BY OTHER CONDITIONS.

A patient may describe his case as one of indigestion when he is not really suffering from any primary affection of the stomach at all: mistakes can be avoided only by subjecting every case to a thorough physical examination of all the organs, and not confining it to the abdomen. If the possibility of error is borne in mind, it is not usually difficult to avoid: and, accordingly, it will be sufficient to enumerate briefly the chief conditions to be thought of. These are:

The Vomiting of Pregnancy.—The possibility of pregnancy should always be present to the mind when one is consulted by a young woman who complains of vomiting and indigestion; the other signs and symptoms of pregnancy (p. 24) should be looked for.

Cerebral Vomiting. In children, particularly, vomiting of cerebral origin may be mistaken for dyspepsia. Incipient meningitis or tumour are the commonest causes of such vomiting. The former, in its earliest stage, may be very difficult to diagnose with certainty, but the presence of signs of cerebral irritation (e.g. photophobia, squint, irritability, headache, Kernig's sign, etc.) should make one suspicious; paralyses, headache, and optic neuritis point to tumour. Examination of the cerebrospinal fluid obtained by lumbar puncture may be required (p. 382).

Uræmia may masquerade as 'indigestion', characterized by loss of appetite and vomiting (uræmic gastritis) in any form of nephritis, but particularly perhaps in cases of enlarged prostate with residual urine, with or without pyuria. The 'uræmic odour' in the breath, high arterial tension, albuminuria, and albuminuric retinitis, should be looked for. It must be remarked, however, that albumin may be absent from the urine in undoubted cases of uræmia.

Phthisis. In cases of early phthisis indigestion may be the chief symptom of which the patient complains, nausea and vomiting being often present. This can be excluded by a careful examination of the chest and of the sputum, which should never be omitted, especially in young subjects.

The Gastric Crises of Tabes are apt to be mistaken for dyspepsia. Paroxysmal vomiting of great violence is the usual form they assume, and they may simulate gastric ulcer or other organic affections of the stomach. If the knee-jerks are absent and the pupils immobile to light the diagnosis is easy, but gastric crises may occur early in a case of tabes before the usual signs of disease of the cord have manifested themselves. One should inquire in such a case for a history of lightning pains, and for any trouble with the bladder. It is said also that the blood-pressure is raised during a gastric crisis, whereas it is lowered in all other cases of acute vomiting.

Nervous or Hysterical Vomiting may also simulate dyspepsia. The diagnosis here must be made largely by the method of exclusion. The patient is usually a woman, and there may be other signs of hysteria present (p. 570).

In **Chronic Intestinal Obstruction** the abdominal pains, and the vomiting which often accompanies them, may be described by the patients as 'indigestion'. In such a case there will be distention of the abdomen, often with visible peristalsis, and a history of gradually increasing constipation. A tumour may be felt, or examination with X rays or with the sigmoidoscope may clear up the case.

Cholecystitis is very apt to be diagnosed as 'indigestion'. In the case of middle-aged or elderly women, particularly, who complain of 'wind' and 'spasms', the possibility of the presence of gall-stones should always be thought of.

Chronic Appendicitis may manifest itself chiefly by symptoms which point to the caecum rather than to the vermiform appendix as the seat of the disease. The pain in such a case may have the character of a typical 'hunger-pain', and be relieved by alkalis. In children who are brought to one for 'indigestion', with vague abdominal pains, the possibility of appendicitis should be specially remembered.

Angina Pectoris in one of its forms may be accompanied by much flatulence, which leads the patient to consult his doctor for 'indigestion'. The occurrence of the symptoms upon exertion, the characteristic tendency of the pain to spread into the left arm, and the frequent presence of a high blood-pressure are all of diagnostic value. *Abdominal angina*, in which the pain is seated in the large abdominal blood-vessels, may be more difficult to differentiate. Flatulence is again a pronounced feature; but there may also be vomiting, and even hæmatemesis. Thickening of the peripheral blood-vessels is usually present; and the therapeutic test is of help, the pain being relieved by vasodilators, such as amyl nitrite or trinitrin, and especially by diuretin.

Migraine.—A patient who suffers from this complaint may describe his case as one of 'indigestion'. The chief diagnostic point is the occurrence of severe headache with or preceding the gastric symptoms, and the marked periodicity of the attacks.

Extra-abdominal causes of Pain are often put down by patients to indigestion. Examples of these are pleurisy, spinal caries, aneurysm, neoplasm of the spine.

Eruclatio Nervosa, due to air-swallowing, is also usually described as indigestion. For the method of diagnosing it, see FLATULENCE (p. 302).

II. FUNCTIONAL VERSUS ORGANIC DYSPEPSIA.

Having excluded all these possible causes of error one may conclude that one has to deal with a case of either organic or functional disease in the stomach itself. If vomiting, loss of flesh, or *severe* pain are prominent symptoms, the disease is probably *organic*: if these are absent, and the affection has persisted for some time, one has most likely to do with a *functional* disorder.

III. DIFFERENTIAL DIAGNOSIS OF ORGANIC DYSPEPSIAS.

The chief organic diseases which have to be thought of are: (1) *Cancer*; (2) *Ulcer*; (3) *Gastritis*; (4) *Obstructive dilatation*.

1. **Cancer.** A malignant growth in the stomach may be situated either at the *cardiac orifice*, in the *body*, or at the *pylorus*. In the first of these situations it will produce difficulty in swallowing. If at the pylorus, it will result in dilatation of the stomach. Growths in the body are those which are most difficult to diagnose.

a. A history of 'indigestion' beginning abruptly in a patient (oftenest a man) above the age of forty, and not yielding speedily to simple treatment, is very suspicious. On the other hand it must be remembered that in a considerable number of cases the growth starts in an old ulcer, so that a long history does not exclude carcinoma.

b. Steady loss of weight, and the early appearance of anemia, point to malignant growth; but, on the other hand, the absence of these signs, and even a temporary gain in weight under treatment, by no means exclude it.

c. Loss of appetite, and especially a disinclination for meat, are usually early symptoms. Nausea and vomiting supervene later but are rarely absent altogether. Pain may be present early, and is often more or less constant. (See PAIS IN THE EPIGASTRIUM, p. 536.)

d. A steady diminution in the amount of hydrochloric acid in the gastric juice, with the presence of lactic acid and of Oppler-Boas bacilli in the gastric contents, is a combination pointing strongly to carcinoma.

It is upon a combination of these symptoms and signs that the clinical diagnosis must be based in the early stage when it is most important to make it. Later, a tumour may be felt below the left costal margin or in the epigastrium: enlarged glands may appear above the left clavicle, although they are exceptional; and there may be signs of secondary growths in the liver or at the umbilicus. When ulceration has supervened, traces of blood may be found in the gastric contents, and occult blood in the stools (p. 104).

X-ray examination is of the greatest diagnostic value in all stages. Filling defects and interference with peristalsis are the points to look for. (See Figs. 277-280, pp. 340, 341.)

In some cases of carcinoma of the body of the stomach pronounced anemia is one of the earliest and most striking symptoms. Such cases have to be diagnosed from pernicious anemia. A blood-count will usually suffice to distinguish them, for in gastric carcinoma the red cells are rarely below 2,000,000 per c.mm., whereas in pernicious anemia they go much lower than that: in pernicious anemia, also, the colour-index is about 1 or above it, in carcinoma it is less than 1. Megaloblasts are found in the film in pernicious anemia, but not in carcinoma. In spite of all that has been said above, the early diagnosis of carcinoma of the stomach is a matter of great difficulty: and it may be justifiable to resort to an exploratory operation in a suspicious case which does not clear up after a few weeks' treatment.

2. **Ulcer.** The characteristic symptom of gastric ulcer is *pain* which comes on after food and is relieved by vomiting, which is usually though not invariably present. The pain occurs in 'attacks' of a few weeks' duration separated by intervals of freedom. Hematemesis is strongly confirmatory, but is often absent. The symptoms will be found on p. 339. Duodenal ulcer is also often associated with symptoms that the patient describes vaguely as 'indigestion': the symptoms are given on p. 342.

The chief *sign* of ulcer is a *localized* spot of tenderness on deep pressure. This, however, is often absent. Occasionally the X rays show a definite outline of the ulcer projecting from the lesser curvature (*Fig. 317*).

3. Gastritis. Chronic 'gastric catarrh' is certainly diagnosed oftener than it should be, the majority of cases so described being really examples of functional dyspepsia. The symptoms are loss of appetite and fullness with a sense of oppressive weight in the epigastrium, *depending greatly upon the kind of food taken*. Pain is not a feature of gastritis; nausea is common, and vomiting may occur but it is not usually a prominent symptom. There is no characteristic physical sign, and a diagnosis cannot be made with certainty without the use of the stomach tube. This shows: (a) Diminished total acidity, or even complete absence of gastric juice; (b) Excess of mucus in the contents, or the presence of mucus on washing out the fasting stomach. Having determined the presence of gastritis, one has to settle whether it is primary or secondary. Secondary gastritis may occur: (a) Where there is disease of the heart, causing back-pressure; (b) In cirrhosis of the liver; (c) In chronic renal disease. If all of these can be excluded, primary gastritis may be diagnosed, and the chief causes of the latter looked for. These are: (a) Defective or carious teeth, and oral sepsis; (b) Abuse of alcohol, tea, or tobacco, or the taking of irritating articles of food.

4. Dilatation. The *presence of dilatation* is determined by: (a) Showing that the stomach is enlarged; and (b) Proving the occurrence of stagnation of the contents.

Fig. 317.—Gastric ulcer. A barium meal has been given, and the barium is projecting into a large chronic ulcer on the lesser curvature, marked by an arrow. The diagnosis was confirmed surgically. (Kindly supplied by Major D. R. McGeorge, R.A.M.C.)

a. Enlargement of the stomach may be inferred when, by percussion, the greater curvature is found to reach below the level of the umbilicus, the lesser curvature being in its normal position. In order to facilitate percussion it may be necessary to inflate the stomach by making the patient swallow 90 gr. of tartaric acid followed by 120 gr. of bicarbonate of soda. Examination by the X rays is the most certain method of demonstrating the real size of the stomach (*Fig. 185, p. 219*). The presence of splashing is not a certain sign of dilatation, unless it is present some hours after a meal, and covers an area greater than the normal stomach should.

b. The occurrence of stagnation of contents is proved by giving the patient an evening meal, preferably containing some easily recognizable food, e.g., currants, and washing out the stomach next morning. If food residues are present in the washings, stagnation may be inferred. Examination with the X rays is a still more certain method of diagnosing delay in emptying the stomach; normally the meal should have left the stomach in four, or at most six hours.

The *cause of dilatation* may be either: (a) Some obstruction at the pylorus; or (b) Primary atony of the stomach wall.

In distinguishing between these, the history may help. Thus the occurrence in the past of symptoms of ulcer points to a cicatricial stenosis of the pylorus. If visible peristaltic waves are seen one may be sure of the existence of an obstruction. These can sometimes be elicited by massaging the stomach or by flicking the surface of the abdomen gently with the fingers or a wet towel. The presence of actual stagnation of the contents is also strongly in favour of obstruction, as this rarely, if ever, occurs in cases of atonic dilatation. Copious vomiting also points to obstruction, as it is exceptional to meet with this symptom in atony. In every case X-ray examination is of great value; in addition to enlargement of the stomach with delay in emptying, strong peristaltic waves with 'reverse' peristalsis can be seen in cases of obstruction.

Assuming that obstructive dilatation has been diagnosed, one has next to distinguish between *benign* and *malignant obstruction*. A history or signs and symptoms of gastric

or duodenal ulcer point to the former; the general symptoms of carcinoma to the latter. A tumour may be felt in either case. Examination of the stomach contents also helps in the differential diagnosis. The presence of abundance of free HCl, with sarcine and yeasts, points to benign stenosis; diminution or absence of HCl with the presence of lactic acid and Oppler-Boas bacilli, to malignancy; skiagrams may clinch the diagnosis (*Figs.* 276-283, pp. 339-343).

One has further to distinguish dilatation from: (a) *Gastropnoxis*; and (b) *Hour-glass stomach*.

a. In *gastropnoxis*, percussion (if necessary after inflation) will show that the lesser curvature is displaced downwards, as well as the greater; but the normal distance between the two curvatures—about four inches—is preserved. In most cases of *gastropnoxis* the right kidney is more or less freely movable, and this affords confirmatory evidence. The X rays (see *Fig.* 436, p. 537) offer the most conclusive proof of the dropping of a stomach.

b. *Hour-glass stomach* may be diagnosed by the following signs:

i. If the stomach is washed out with a known quantity of fluid, e.g., 30 oz., it will be found that some has been lost, e.g., 6 oz., when the return fluid is measured. Some of the fluid seems to disappear, in fact, as if it had flowed through a hole.

ii. If the stomach is washed clean, and the tube passed again a few minutes later, several ounces of fermenting liquid may be obtained which have escaped from the pyloric pouch.

iii. If the stomach is drained apparently dry, a splash can still be obtained over the pyloric end ('paradoxical dilatation').

iv. If the stomach resonance is percussed out carefully, and the viscus is then inflated with tartaric acid and soda, as described above, and then again percussed, it will be found that a great increase in resonance has occurred at the cardiac end only. If the abdomen is watched for a little, the pyloric pouch may sometimes be seen to fill gradually and become prominent. A loud gushing sound can also be distinguished on listening with the stethoscope over the site of the opening between the two pouches.

v. X-ray examination will show the division of the stomach into two pouches (*Fig.* 275, p. 339), and this method when available supersedes all other methods of diagnosis, though it is important not to mistake for organic hour-glass stomach the physiological behaviour of stray peristaltic waves which may produce an hour-glass appearance in a photograph; screen examination shows the constriction to be inconstant in position in the latter case, always in the same place in the former.

IV. DIFFERENTIAL DIAGNOSIS OF FUNCTIONAL DYSPEPSIA.

Assuming that all the above forms of organic disease can be excluded, one may conclude that the case is one of functional dyspepsia.

The next task is to determine what particular variety of functional disorder one has to deal with. In attempting to do this one is met at the outset by the difficulty of classifying functional disorders of the stomach. Three forms of classification may be adopted: (1) *Physiological*; (2) *Clinical*; (3) *Etiological*.

1. **Physiological Classification.** In this classification, cases of functional dyspepsia are arranged according to the particular function affected, thus:

a. *Affections of secretion*:

- i. Excess—Hypersecretion and hyperchlorhydria.
- ii. Defect—Achyia and hypochlorhydria.

b. *Affections of motility*:

- i. Excess—Pyloric or gastric spasm.
- ii. Defect—Atony, or impaired motility.

c. *Affections of sensation*:

- Excess—Hyperaesthesia or gastralgia.

Any of these may be present alone, or two or more may exist in conjunction.

The diagnosis of affections of secretion and mobility can be made by the aid of the stomach tube and by the X rays. These are undoubtedly the most scientific methods

of making a differential diagnosis in cases of functional dyspepsia, and both lines of investigation are wise notwithstanding the inconvenience to the patient of giving and recovering test meals.

For the diagnosis of hyperæsthesia (gastralgia), see PAIN IN THE EPIGASTRIUM (p. 536).

2. Clinical Classification.—Clinically, cases of functional dyspepsia may be classified into certain rough groups according to their symptoms. Thus :

a. Hypersthenic or Hypertonic Dyspepsia. This is probably due to a combination of hypersecretion and hyperæsthesia. The patient is usually a young man otherwise healthy, and the chief symptom is pain during the late period of digestion. It is apt to go on to the formation of a duodenal ulcer.

b. Asthenic or Atonic Dyspepsia.—This is due to impaired motility (atony), with or without some disorder of secretion. The patient may be of either sex, of any age, and the chief symptoms are flatulence and fullness. It is often present along with gastropptosis, especially in women ; and there may be atonic dilatation of the stomach.

c. Acid Dyspepsia. This is an ill-defined group in which the chief symptom is a sensation of acidity, or the presence of acid eructations. Some cases are really examples of hyperchlorhydria, with or without the presence of gastritis. In others, the cause is the production of organic acids by fermentation. Diagnosis can only be made by aid of the stomach tube and analysis of a test meal : one of the simplest of which, taken on an empty stomach in the morning, is a pint of tea of which one third is milk, with sugar to taste, and two ordinary triangles of toast lightly buttered but well masticated so as not to obstruct the opening in the tube ; the latter is passed exactly one hour after the test meal, and the maximum free HCl should not exceed 0.2 per cent.

Other clinical forms of dyspepsia are also described, e.g., 'senile' dyspepsia (essentially a hypochylia), 'gouty' dyspepsia (the same as the 'acid' form), 'flatulent' dyspepsia (usually due to defective motility) ; 'gall-stone' dyspepsia or indigestion associated with gall-stones which do not produce acute colic or jaundice ; 'appendicular' dyspepsia, when the symptoms appear to be gastric, though in reality the trouble lies in the right iliac fossa and is relieved only by appendicectomy ; and others ; but the use of such terms is inaccurate, and should be avoided as far as possible.

3. Etiological Classification. Instead of attempting to distinguish different forms of functional dyspepsia one can regard the latter as an aggregation of symptoms of gastric disorder excited by different causes, and classify cases according to the particular exciting cause at work. This method is simple and convenient, and is also useful for purposes of treatment. Adopting it, one may say that functional dyspepsia may be induced by :

a. Dietetic causes, e.g., unsuitable food, hasty meals, the abuse of alcohol, tobacco, tea, etc.

b. Physical causes, e.g., imperfect chewing, defective teeth, oral sepsis, over-fatigue, deficient exercise, etc.

Mental causes, e.g., over-work, a studious life, etc.

Emotional causes, e.g., shock, worry, love-affairs, etc.

Any of the above methods is useful, the essential point being that a classification of some sort should be adopted. Probably a combination of the first and third methods, which take into account both the particular disorder which is present and the cause which has brought it about, will lead to the best treatment.

METHODS OF EXAMINING THE STOMACH.

The following is a brief account of some special methods employed in examining the stomach, which are capable of being carried out in ordinary practice :

1. Determination of Size. This is done by light percussion, or by percussion-auscultation, with or without previous inflation. The position of the lesser and greater curvatures and of the fundus must be determined. Inflation is performed either : (*a*) Through a stomach tube connected with a Higginson's syringe ; or (*b*) By making the patient swallow 90 gr. of tartaric acid dissolved in three ounces of water, followed by 120 gr. of bicarbonate of soda. The only really adequate method of determining the size of the stomach, however, is by an X-ray examination after a bismuth or barium meal.

2. Investigation of the Contents.—A test meal, consisting of two slices of dry toast and two cups of tea with a little milk, is given in the morning, and the tube passed an hour later. The tube should have a solid end and one bevelled lateral eye close to it. The sample drawn off should be investigated as regards :—

a. Quantity. A very small result containing little fluid indicates diminished secretion (achylia) or very rapid emptying (duodenal ulcer, hypermotility); an abundant and very liquid yield indicates diminished motility or pyloric stenosis.

b. Physical Characters. The presence of large pieces of but slightly altered food indicates defective secretion and digestion; a large amount of liquid with a granular deposit shows hypersecretion. A very sour odour reveals the presence of organic acids. Viscidity of the contents, so that they filter slowly, is characteristic of the presence of mucus in excess.

c. Acidity.

i. *Test for Free HCl.* Congo-red paper is turned blue, methyl-orange paper red, if free HCl be present. The depth of colour indicates approximately the amount of free acid. Proof of free HCl is given by Gunzburg's test (Fig. 318).

ii. *Total Acidity.* Ten c.c. of the filtered contents are titrated with decinormal caustic soda solution, two or three drops of phenolphthalein solution being used as an indicator. A pink tinge appears as soon as the acidity has been neutralized. The result is expressed in terms of the amount of caustic soda solution required to neutralize 100 c.c. of the gastric contents: e.g., if 6 c.c. neutralize 10 c.c. of the contents, then the acidity is 60. The normal acidity is between 40 and 70.

iii. *Organic Acids* need only be tested for if free HCl is absent. A sour odour of the contents indicates their presence; acetic acid and butyric acid can be recognized by the odour of vinegar or rancidity respectively; lactic acid by adding a few drops of the contents to some Uffelmann's reagent (equal parts of 1-20 carbolic and weak liq. ferri perchlor.) in a test tube; a bright yellow colour is produced if the acid is present.

d. Ferments. Rennin can be tested for by neutralizing some of the contents, and trying whether the addition of a few drops to a little milk results in coagulation when kept warm for twenty minutes.

There is no convenient test for pepsin, but its absence may usually be inferred if there is no rennin present.

e. Microscopical Characters. Films are made from some of the deposit, and stained with dilute gentian violet. Oppder-Boas bacilli, yeasts, and sarcinae (Fig. 258, p. 302) should be looked for. The first occur specially in cases of carcinoma; the two last in benign stenosis of the pylorus.

3. **The Fractional Test-Meal** is too time-consuming to be of use in ordinary practice, nor is the additional information which it supplies of sufficient value to compensate for this disadvantage. Those who wish to use it should consult special treatises.

4. **Determination of Motility.** Impaired motility is shown by the presence of food residue in any quantity (say about 4 ounces) six and a half hours after an ordinary dinner. In order to prove the presence of stagnation, a light meal, preferably containing some easily recognized food (e.g., currants), should be given in the evening, and the stomach washed out next morning. If the currants or other similar food be found in the washings, stagnation exists. If there is no recognizable food from the previous day, but if several ounces of greenish acid fluid are obtained, hypersecretion is present; flakes of mucus may be found in the washings in gastritis.

INSOMNIA means inability to obtain the normal amount of sleep. It includes sleeplessness and broken or restless sleep, and admits of no closer definition because the normal amount of sleep varies widely with age, habit, and idiosyncrasy. Thus, out of the twenty-four hours, an infant at one month will sleep for twenty-one, at six months for eighteen,

at twelve months for fifteen hours. A child four years old needs twelve hours' sleep, the schoolboy of twelve needs ten, the public-school man should have nine. The average hours of sleep in adult life are said to be eight for women, seven for men, but idiosyncrasy may cut down the hours necessary in certain people to no more than three or four, for long periods and without any impairment of health or the power to work. Habit may train neglected children or overworked labourers and servants to get on with short hours of rest and interrupted sleep that would speedily make an ordinary person ill. Insomnia is a symptom indicating that something is amiss, not a disease *per se*. It occurs in a great many acute and chronic disorders, but in most cases it depends on functional disturbances, faulty habits of hygiene, an ill-arranged regimen, and not upon organic disease. Most patients habitually underestimate the amount of sleep they get, without any intention to deceive: and are apt to complain that they have been awake all night when in point of fact they have had many hours of sleep.

The chief causes of insomnia are tabulated below in three main groups, etiologically:—

1. Insomnia due to Faulty Habits or Hygiene, such as

Some sudden change in the routine of the day or evening
Exposure to undue excitement or bad atmosphere before retiring
The use of a noisy, airless, or overheated bedroom
The use of too many bedclothes, or too few
Going to bed on too full or too empty a stomach
Drinking strong tea or coffee too late in the day
The over-use of tobacco.

2. Insomnia due to Acute Disorders, such as

Pain due to any cause, inflammation, injury, neuritis, etc.
The early stages of fevers
Acute insanity, meningitis, delirium tremens, acute mania, etc.
Acute nervous exhaustion.

3. Insomnia due to Chronic Disorders, such as—

Gastro-intestinal disorders, dyspepsia, constipation, etc.
Chronic insanity of all sorts, neurasthenia
Cerebral syphilis, intracranial tumour
Disease of the heart, valvular or myocardial
Disease of the lungs, emphysema, bronchitis, asthma, etc.
Diseases of the liver or kidneys
Arteriosclerosis and high blood-pressure, hyperpiesis
Anæmia, primary or secondary
Hysteria and malingering.

The closer investigation of the causes of insomnia may best be done by taking the case of the patient into consideration.

Sleeplessness in an Infant is most often due to indigestion, hunger, or bodily discomfort: in rare cases it is evidence of nervous instability or ear or brain disease. Inquiry into the methods and hours of feeding the infant will often show where the fault lies: the food may be improper, the hours of feeding too frequent, the practice of giving the bottle or **breast** whenever the infant cries may have been followed, or the habit of allowing it a dummy teat to suck at all hours. The artificially fed infant is likely to suffer from indigestion and colic, with screaming, drawing up of the legs, and rigid abdomen: the breast-fed infant will more often fail to sleep because it is hungry. In many cases it fails to sleep because it is in discomfort from a wet napkin or bed, from having too many bedclothes and being overheated, or from being cold: the bedroom may be too light or too noisy. In not a few instances it fails to sleep well for want of proper training: especially if it finds that it will be fed or rocked in the arms or cradle as often and as long as it sees fit to cry. When the infant is six months old or more, rickets and the local irritation of teething are common additional causes. In a minority of cases the sleeplessness is due to the onset or presence of acute or chronic disease, or to the indeterminate condition described as nervousness or nervous instability, or to definite mental deficiency: careful examination of the infant and its previous history should suffice to clear up the diagnosis in these cases. As the treatment of sleeplessness in an infant hardly ever demands the use of sedative drugs, but

consists mainly in rectifying errors of diet, hygiene, or up-bringing, it is obvious that the medical man must be prepared to go deeply into these domestic—rather than medical—matters.

Sleeplessness in Children is due largely to causes similar to those described above. In a great many cases it is due to indigestion, with which may be associated flatulence, teething, and the presence of worms in the intestine: tea-drinking is a common cause of chronic dyspepsia, nervous irritability, and disturbed sleep, in children as well as in adults. Many children sleep ill because they are put to bed within an hour or so of a late tea or early supper of too solid a character: others, for want of fresh air in the bedroom, waking late on the following morning in a headachy and irritable condition and with little appetite for breakfast. Not a few ill-fed or anæmic school-children sleep badly during term-time because they are overworked, or worried about their lessons or their place in class without being actually overworked: in such cases the distraction afforded by games is likely to be more successful in effecting a cure than treatment by rest. It is only in the minority of instances that the insomnia is due to disease, whether acute or chronic, such as adenoids, enlarged tonsils, or organic disease of the various viscera. A few special forms of insomnia seen in childhood call for brief mention. In *early hip disease* sleep may be disturbed by sudden starting pains: the child goes off to sleep, only to be awakened almost at once by sudden shooting pains in the affected leg or hip. Sleep is broken by fright in *night-terrors* (see NIGHTMARES, p. 499), in which the child wakes up screaming and frightened, but conscious and able to explain, so far as excitement permits, the nature of the fright: indiscretions in diet, or the presence of adenoids or worms, often explain the occurrence of such night-terrors. In the rarer and more serious form of night-terror, known as *pavor nocturnus*, the child awakes, screaming and frightened, but not fully conscious, and unable to recognize those around him. There is no recollection of the fright next day, and in all probability the pavor is akin to epilepsy, occurring mainly in children with a bad family history of nervous disease. It is plain from what has been said above that the diagnosis of the cause of sleeplessness in a child demands scrutiny of the daily routine, diet, and sleeping arrangements, as well as examination of the child itself. Sedative drugs are practically never required for its treatment, except in the case of severe acute or chronic disease, and even then should be given but rarely.

Insomnia in Adults, in the majority of cases, is due to faults of *habit* or *hygiene* similar to those already mentioned in the case of children: but it is due to organic disease of one sort or another in not a few instances, discussed later. The sleepless adult should devote thought to the economy and arrangement of his bed and bedroom, and the hours he keeps. The bed should be comfortable—whether the mattress be hard or soft is a matter of taste: many people sleep better with a high pillow than with a low, and if a high pillow is not agreeable, the same effect can often be produced by putting blocks two or three inches high beneath the posts at the head of the bed. The bedclothes should be light rather than heavy: they should be warm enough to prevent the occurrence of cold feet, a very common cause of sleeplessness. The bed should not be placed so that the sleeper faces the light. A supply of fresh air throughout the night is essential, and is assured if the room is heated by an open fire: stulliness and overheating of the atmosphere seem almost inseparable from heating by stoves, gas-fires, hot air, hot water, or steam, and are common causes of sleeplessness. The hygiene of the bedroom having been attended to, the *habits* of the sleepless patient should be passed in review. Many well-to-do people sleep ill because they go to bed too soon after a heavy dinner: a few because they go to bed hungry. Not a few find that they sleep badly if they take a cup of coffee after dinner, or even drink tea in the afternoon: others sleep ill if they indulge in brain-work after dinner, or attend exciting public meetings, theatres, concerts, and so forth. It is known that bodily and mental fatigue promote sleep, and some patients with insomnia solicit sleep and aggravate their condition by pushing fatigue to the point of exhaustion, forgetting that over-fatigue often produces sleeplessness. The observance of fairly regular hours for work, food, and sleep is often neglected by busy men, and the neglect frequently results in disturbance of their sleep. Sudden changes in the mode or routine of daily life, or alterations in the altitude or locality inhabited, may result in acute and persistent insomnia. It is to the investigation of these and similar irregularities, trifling as many of them may appear, that one must look in diagnosing the cause of insomnia in healthy or fairly healthy

patients : its treatment will naturally turn mainly on their correction. Healthier habits of life must be advised, and the use of sedatives avoided if possible.

In the case of adults suffering from the most various *acute disorders*, slight or severe, the occurrence of insomnia is a commonplace. It passes off with the amelioration of the disorder, and if the patient is able to give an account of himself and of his symptoms, the diagnosis should not be difficult.

It is often otherwise with adults suffering from insomnia due to *chronic disease* : the sleeplessness may be one of the earliest symptoms of illness, or the other symptoms that are present may have escaped the patient's notice. For example, persistent inability to sleep is often a prominent and early feature of *nervous* or *mental disease*—melancholia, mania, general paralysis, hypochondriasis, neurasthenia, acute nervous exhaustion, paralysis agitans, and chronic alcoholism may here be mentioned : in old age, senile nocturnal mania may occur as a very troublesome form of insomnia. Inability to sleep may be marked in cases of cerebral tumour or cerebral syphilis. Want of sleep throws a great strain on the nervous system generally, and so is a prominent factor in the production of insanity : the one aggravates the other, and a vicious circle is established. In *heart disease*, insomnia is frequently a distressing feature : the patient often has to sleep propped up in bed because of breathlessness whenever the recumbent position is adopted, and when he does get off to sleep he is often awakened by cardiac palpitation or dyspnoea, within a few minutes. Restless nights are passed even while cardiac compensation is maintained : when compensation fails the condition is much aggravated. Patients with aortic incompetence may be kept awake by the pulsating shock and noise of their own hearts. Dyspnoea is a common cause of sleeplessness in many *diseases of the lungs*. Patients with bronchitis, emphysema, spasmodic asthma, extensive pulmonary adhesions, or pulmonary tuberculosis, and other kindred diseases, often pass restless nights because they are awakened by pulmonary dyspnoea soon after getting off to sleep. With these patients, as with those suffering from heart disease, the sitting or semi-recumbent position at night is often imperative, the reasons being that diaphragmatic breathing is easiest, and the amplitude of the diaphragmatic movements is greater when the patient sits than when he lies. Sleeplessness is frequent in *cirrhosis of the liver*, being accompanied by nocturnal delirium in the severer cases : it may also occur in *chronic renal disease*. It is often a persistent and distressing feature of *arteriosclerosis* and *high blood-pressure*, with hypertrophy of the heart. The mechanism whereby this sleeplessness is produced is obscure : but from the fact that any treatment that lowers the blood-pressure—massage, hot baths, high-frequency currents of electricity—cures the insomnia, it may be assumed that the high arterial pressure acts directly, preventing the establishment of the degree of cerebral anemia that is requisite for sleep. But it must be noted that if insomnia results from the supply of too much blood to the brain, it also results from the supply of too little : hence sleeplessness occurs in *grave anemia*, whether primary or secondary.

In conclusion, it may be noted that in *hysteria*, professions of obstinate insomnia go beyond the observed facts : and that the *malingerer*, claiming not to have slept at all for days or weeks, may urge the sound slumber he enjoys in hospital as an argument for the prolongation of his stay.

IRIDOPLEGIA.—(See PUPIL, ABNORMALITIES OF THE, p. 674.)

IRITIS.—(See EYE, ACUTE INFLAMMATION OF, p. 285.)

IRRITABILITY. It is not very often that irritability can be regarded as a symptom of diagnostic importance. It is a relative condition, varying in its significance with the individual, and more especially with his age. Children, for instance, display irritability

much more readily than adults under similar influences owing to incomplete education of their powers of control, and a like distinction may be drawn between different persons of adult age. Varying degrees of irritability may be recognized under any condition of ill-health, and as a solitary symptom it can hardly be regarded as one of much import. An exception may perhaps be made in favour of the steadily increasing irritability which is sometimes observed as a prodrome of *meningitis*, and which may be sufficiently remarkable to instigate a careful look-out for other early signs of that disease, such as vomiting, headache, strabismus, and head-retraction.

In adults, the personal disposition is longer established and better recognized, so that definite alterations in temperament, independent of obvious cause, and clearly not of fleeting character, must always receive attention from the medical man to whose notice they are brought. Many chronic ailments, especially those which entail mental or physical suffering, may be associated with increased irritability without exciting special remark. On the other hand there are some constitutional or metabolic disturbances which are noted for the irritability to which they may give rise. *Diabetes mellitus* and *chronic nephritis* are common examples of this kind, and the examination of the urine of patients in whom friends have observed, or who may even themselves complain of, irritability, should never be neglected. In such conditions as *jaundice*, *Graves' disease*, and *acromegaly*, other symptoms and signs are more obvious and more conclusive.

Irritability often forms part of a *neurasthenic syndrome*, but it is well to remember that the same symptom may be present in the early stages of *general paralysis of the insane*. A careful investigation of other mental changes, of the condition of the reflexes and pupils, and, if suspicion is aroused, a Wassermann test, should be carried out before coming to a definite diagnosis. In lethargic encephalitis a phase of irritability not infrequently precedes the drowsy state so characteristic of that disease, and may form part of the mental disturbances persisting after the more acute symptoms of illness have passed off. It is hardly necessary to add that irritability may be associated with other depressed mental states, such as *melancholia* and *epileptic dementia*. Finally, chronic intoxications, and especially *chronic alcoholism* and *plumbism*, may be responsible for great irritability, especially in the earlier hours of the day.

IRRITABILITY OF THE BLADDER. (See MICTURITION, ABNORMALITIES OF, p. 490.)

ITCHING. (See PRURITUS, p. 658.)

JAUNDICE is the term used to indicate the yellow or greenish-yellow coloration of the skin, conjunctiva, mucous membranes, and other tissues and fluids of the body, by bile pigment. The following are its chief signs:

The Skin. The colour varies from a light sulphur yellow to a deep orange, greenish, and, in some cases, dark olive tint. The greenish or dark olive shade is only found in severe cases of long standing. Intense itching is often produced, especially if the jaundice is the result of obstruction of the bile-ducts; and this sometimes leads to vigorous scratching and the production of scratch-marks, blood-crusts, and sore places.

In certain cases, after some time, yellowish-white or light yellowish-salmon-coloured patches of soft smooth tissue slightly raised above the surface of the surrounding skin may appear on the upper eyelids near the inner canthi—*xanthelasma palpebrarum* (Fig. 319). These patches may spread until the eye is surrounded entirely by this altered skin. A similar condition may also occur on the palmar surface of the hands and fingers, or firm rounded nodules varying in size from $\frac{1}{4}$ in. to $\frac{1}{2}$ in. in diameter, more or less raised above the level of the surrounding skin, may develop over the elbows, knees, or in other places—*xanthelasma planum* and *xanthelasma tuberosum*.

The Eyes. The conjunctiva are yellow. Care must be taken to distinguish deposits of subconjunctival fat from actual coloration. Occasionally, it is said, patients suffer from yellow vision (xanthopsia), but this is really a most uncommon symptom even in the most jaundiced cases.

The Urine may present almost any shade of coloration by bile-pigments, from a light saffron-yellow to yellowish-brown, medium brown, dark mahogany brown, greenish-brown, or even almost black. On looking across the upper portion of the urine in a specimen

glass a distinct greenish tinge may be detected, and the froth which forms at the top on shaking possesses a distinct yellowish or greenish shade. It stains white blotting-paper and linen a bright yellow.

As a general rule, when jaundice is developing, bile pigment can be detected in the urine before the conjunctivæ become yellow, and the conjunctivæ become jaundiced before the

Fig. 319.—Xanthelasma palpebrarum.

skin. On the other hand, when jaundice is leaving a patient, the bile pigment disappears first from the urine, the skin remaining coloured for some time afterwards. There are certain special cases in which the skin and conjunctivæ exhibit obvious jaundice, yet there is no bile pigment in the urine, a state of affairs that is termed acholuric jaundice (pp. 414, 415).

Other Secretions.—The sweat, and the milk of women who are nursing, may be tinged yellow. Pleuritic, pericardial, or peritoneal effusions may be similarly coloured. The tears, saliva, and gastro-intestinal secretions are not affected in this manner, nor are the meninges, brain, spinal cord, or cerebrospinal fluid.

The Fæces.—In cases of jaundice due to obstruction of the larger ducts the fæces become greyish-white or clay-coloured from lack of stercobilin, and they may contain an

Fig. 320.—The iodine test for bile in urine.

Fig. 321.—Gmelin's reaction for bile pigment in urine.

Fig. 322.—The fluorescence reaction of urobilin.

excess of fat which by decomposition is likely to give the stools a very offensive smell. The bowels are usually constipated.

The Pulse.—It is frequently stated that the pulse is apt to become much slower than normal as the result of jaundice. It is, however, very rare to find these slow-pulse cases clinically; more often, although physiological experiments show that the bile salts tend

to slow the heart remarkably, the pulse-rate in jaundiced patients is either normal, or accelerated, especially in pyrexial cases.

Bruising. There is a marked tendency to capillary oozing and hæmorrhage in certain cases: this is important, not only from the point of view of operations and the liability to blood-oozing after them, but also because of the ready bruising of the skin which might be mistaken for evidence of violence.

Cholæmia. In cases of severe or long-continued jaundice, cholæmic symptoms may supervene, namely, stupor, delirium, convulsions, coma, and death.

Bile pigment in the urine is generally tested for by Gmelin's test or the iodine test (*Figs. 320, 321, and p. 903*).

Jaundice must not be mistaken for other conditions which cause yellowness of the skin. Slight jaundice and pernicious anæmia are perhaps the two conditions that may most readily be mistaken for each other: in the latter, however, the conjunctivæ are generally of a pearly whiteness, however yellow the skin may be: and if the urine should be suspiciously dark, its colour will be found to be due to urobilin, detected by its spectroscopic band between the E and F lines (*Fig. 23, p. 13*), whilst tests for bile pigments would be negative. If there is doubt as to the presence of urobilin on direct spectroscopic examination, or if no spectroscope is available, the following test may be employed: A quantity of the urine, say an ounce, is poured into a suitable glass cylinder and acidulated with a few drops of acetic acid: about half an ounce of amyl alcohol is then added, and the mixture shaken slowly to and fro in the cylinder several times, after which it is allowed to stand for some minutes whilst the amyl alcohol separates to the top: the urobilin is now in solution in the amyl alcohol, which may be poured off into a test-tube: on adding a few drops of a saturated solution of zinc acetate in ethyl alcohol to it, a beautiful red-green-yellow fluorescence results if urobilin is present, the appearance being similar to that of a weak solution of eosin (*Fig. 322*): and the absorption band of urobilin can be seen readily through it with the spectroscope.

In very occasional cases of pernicious anæmia there may be real jaundice in addition to urobilinuria: but although the blood serum in pernicious anæmia generally exhibits a yellow tint from excess of bile pigments, it is rare to find true jaundice in this disease.

Acholic jaundice cases are probably the most difficult to be sure of, for in these, though the conjunctivæ may be definitely yellow, the urine shows no obvious bile-pigment coloration.

Having concluded that a patient has jaundice, the next step is to decide between the causes of the symptom. The following are the chief of them:—

CAUSES OF JAUNDICE.

I. Jaundice due to Obstruction of the larger Bile-ducts, especially of the Common Bile-duct:—

A. Causes within the Duct:

Gall-stones	Parasites	Distomata
Insprissated bile		Ascarides.

B. Causes affecting the Wall of the Duct:—

Catarrh of the mucous membrane of the duct	Catarrh of the pancreas spreading to and involving the ampulla of Vater
Catarrh of the mucous membrane of the duodenum involving and obstructing the ampulla of Vater	(Chronic pancreatitis)
	Carcinoma of the duct
	Cicatrization following ulceration of the duct
	Congenital obliteration of the duct.

C. Causes Compressing the Duct or Invading it from the Outside:—

Peritoneal adhesions	Tumours of the stomach
Enlarged portal lymphatic glands:	“ “ colon
<i>a</i> Secondary malignant	“ “ right kidney
<i>b</i> Lymphadenomatous	“ “ right suprarenal capsule
<i>c</i> Tuberculous	“ “ ovaries
<i>d</i> Leukæmic	“ “ uterus
<i>e</i> Secondary syphilitic	“ “ omentum
Tumours of the liver	Aneurysm of the hepatic artery
“ “ pancreas	Hydatid cyst
“ “ duodenum	Retroperitoneal cyst.

II. Jaundice without Obstruction of the larger Bile-ducts :—

A. Causes associated with Disease of the Liver : —

Carcinoma	Acute yellow atrophy
Cirrhosis	Passive congestion from chronic heart failure
Abscess : Single	Syphilis
Multiple or pyæmic	Active congestion (Tropical hepatitis).

B. Jaundice in Acute Fevers and Infections, such as : —

Malaria	Influenza of septic type	Epidemic catarrhal jaundice
Typhus fever	Pneumonia	Yellow fever
Typhoid fever	Weil's disease (Spirochaetosis	Relapsing fever
Pyæmia	icterohæmorrhagica)	Some other tropical fevers.

C. Jaundice due to Poisons :—

Phosphorus	Seleniuretted hydrogen	Dinitrobenzene
Phosphoretted hydro-	Male fern	Chloride of sulphur
gen	Toluylenediamine	Chloroform
Arseniuretted hydro-	Trinitrotoluol	Mushroom poisoning
gen	Trinitrophenol (picric acid)	Snake poison
Antimoniuretted hy-	Dinitrophenol	Arsenobenzol compounds.
drogen	Tetrachlorethane ("aeroplane	
	dope")	

D. Jaundice due to Nervous Causes : —

Mental emotion	Concussion.
----------------	-------------

E. Jaundice due to Unclassified Causes : —

Icterus neonatorum	Familial jaundice	Leukæmia
Icterus gravis of in-	Pernicious anæmia	Lymphadenoma
fants	Splenic anæmia	Paroxysmal hæmoglobinuria.
Acholic jaundice		

THE DIAGNOSIS.

When diagnosing the cause of jaundice in any given case it is important to consider, not only the degree of jaundice, but also the age of the patient, the history, and the significance of any other symptoms which may be present.

Very intense jaundice and clay-coloured motions indicate some obstruction to the common bile-duct, the commonest cause being catarrh, gall-stones, chronic pancreatitis, or carcinoma.

Jaundice with rigors suggests : (1) Infective or suppurative cholangitis, with or without suppurating gall-bladder from gall-stones or from carcinoma ; (2) Infective or suppurative pylephlebitis, especially after appendicitis ; (3) Hepatic abscess (single or pyæmic).

Almost all the different causes of jaundice may also cause pyrexia, so that without rigors the existence of pyrexia does not assist greatly in the differential diagnosis. That cirrhosis of the liver and carcinoma of the liver are both very apt to cause evening rises of temperature, to as much as 100° F., 101° F., or more, is a fact that is sometimes overlooked (*Fig. 66*, p. 47, and *Fig. 323*).

Fig. 62b. Temperature chart from a fatal case of secondary carcinoma of the liver.

The absence of pyrexia in a jaundice case will serve to exclude such conditions as abscess, pylephlebitis, cholangitis, acute specific fevers such as typhoid or Weil's disease, and epidemic infective jaundice.

Jaundice with enlargement of the liver may occur in any condition of obstruction to the common bile-duct, and in congestion of the liver, cirrhosis, carcinoma, syphilis, abscess, phosphorus poisoning.

Jaundice with a very greatly enlarged gall-bladder, especially persistent jaundice in a middle-aged person, suggests infective cholecystitis, empyema of the gall-bladder, chronic pancreatitis, or carcinoma of the head of the pancreas. Gall-stones seldom cause both jaundice and a large gall-bladder at the same time, perhaps because the infective

process that produces the gall-stones also causes peritoneal adhesions about the gall-bladder which tie it down and prevent it from expanding.

The diagnosis is very often almost obvious. For instance, jaundice appearing in an infant two or three days after birth, and rapidly disappearing again, is almost physiological (*icterus neonatorum*). Transient jaundice in an otherwise healthy boy or girl will almost certainly be catarrhal. Jaundice following an acute attack of colic at once suggests a gall-stone. Recurrent attacks, extending over years, are not likely to be due to malignant disease, whereas persistent and deepening jaundice without intense pain in a person over 40 years of age, who has been wasting and has only been ill a month or two, suggests malignant disease. It often happens that the primary growth in cases of secondary malignant jaundice is not at once obvious, and it is important not to omit a rectal examination, lest there be a rectal carcinoma that is itself causing no symptoms.

Fig. 324. Skiergram of a catarrhal gall-stone indicated by an arrow; it covered approximately what the stomach was doing. (X-rayed after a bromine meal. (By Dr. W. H. Coldwell).)

The main causes of jaundice may be discussed in a little more detail as follows :

I. OBSTRUCTION OF THE COMMON BILE-DUCT.

1. Within the Duct.

Gall-stones may give rise to no symptoms so long as they remain in the gall-bladder. They vary in size from a gram of sand to a hen's egg, and in a few cases they may be detected by the X rays (*Figs. 324, 325*). If impacted in the cystic duct, distention of the gall-bladder may follow, but there is no jaundice. When impacted in the common duct, intense jaundice is produced, and some enlargement of the liver, but in the majority of cases no distention of the gall-bladder. Impaction of the calculus in the neck of the gall-bladder, or in any of the ducts, or its forcible propulsion along either cystic or common bile-duct,

Fig. 325. Skiergram of gall stones in the gall-bladder; six definite and largest stones can be seen, indicated by arrows. (By Dr. W. H. Coldwell.)

tends to cause intense, agonizing, colicky pain ('biliary colic') which is first felt in the epigastrium and right hypochondrium, extending thence to the back of the lower part of the right chest, to the back of the right shoulder, and over a variable extent of the upper half of the abdomen, or even all over the latter; it may be so severe that the patient becomes collapsed. Vomiting, pyrexia, and rigors are frequently associated with these attacks of pain. The latter lasts a varying time according to what happens to the calculus. It may remain impacted, with repeated recurrence of colic; it may fall back into the gall-bladder so that all symptoms disappear for the time being; or it may pass on into the duodenum, when the severe pain ceases almost suddenly, and the gall-stone may be found in the faeces; if it is faceted other gall-stones are present, and further attacks of colic and jaundice are probable. Sometimes, instead of amounting to colic, the pains caused by gall-stones are more like those of recurrent indigestion, or of gastric or duodenal ulcer—'gall-stone dyspepsia'; and in such cases a duodenal ulcer may be simulated even as regards 'hunger pain'.

Jaundice dependent on the passage of gall-stones usually comes on about twelve hours after the commencement of the attack of colic, and persists for a varying period according to the length of time the calculus remains in the common duct. Occasionally jaundice occurs without any previous colic. Recurring attacks of jaundice in a middle-aged woman, with or without attacks of colic, are almost pathognomonic of gall-stones; only one other disease produces precisely similar symptoms, namely, chronic pancreatitis. In the latter, however, the jaundice is apt to persist longer, and it may never go completely away, lessening between the attacks, to deepen again with each recurrence of the acute pancreatic pain. It is often very difficult without laparotomy to distinguish gall-stones from chronic pancreatitis.

There are, however, several methods of detecting pancreatic disease, most of which depend upon the non-entry of the pancreatic juice into the intestine. The percentage of fat in the stools when ordinary quantities are given by the mouth is very much greater when the pancreatic juice fails than when the bile alone fails, so that extremely fatty iridescent stools favour a diagnosis of pancreatitis or pancreatic neoplasm. The same indication is afforded when the faeces contain a large number of undigested muscle fibres; also when keratin-coated capsules are passed undigested, or when such capsules containing methylene blue are given without the urine subsequently turning blue. Other tests concern the tryptic activity of the motions, and so forth, and their value is still *sub judice*. The subject is discussed under CAMMIDGE'S PANCREATIC REACTION, p. 128.

If a stone remains impacted in the common duct, the jaundice is intense; but if it soon passes into the duodenum, the jaundice is slighter and transient.

Inspissated Bile is always mentioned as a cause of jaundice, but there are no distinguishing signs of this condition, and it would require considerable boldness on the part of the physician to make this the sole diagnosis. Thickening of the bile may occur in acute fevers, poisonings, and so forth, and this is possibly the cause of the jaundice in many of the cases where there is no obstruction to the large bile-ducts; but a diagnosis of 'inspissated bile' by itself would clearly be incomplete and inadequate.

Hydatid cysts. A *hydatid cyst* of the liver may happen to be in such a position as to stenose the common bile-duct, or it might open into the gall-bladder, cystic, hepatic, or common ducts. It is, however, an exceptionally rare cause of jaundice, and it could seldom be diagnosed without resorting to laparotomy.

Distoma hepaticum. The normal habitation of this parasite is the bile-ducts of the sheep; it is sometimes found occupying a similar position in man, though in England this is of extreme rarity. The chief symptoms are jaundice, ascites, enlargement of the liver, vomiting, pyrexia, diarrhoea, and pain in the right hypochondrium. If circumstances should suggest this infection, the vomit and the stools should be examined for flukes, and the stools for ova, which are large, brown, and operculated, measuring 0.13 by 0.08 mm.

Ascaris lumbricoides (round worm). This parasite inhabits the upper part of the small intestine and measures from 15 to 45 cm. in length. It seems to have a special tendency to force itself into small orifices, and it has been recorded as becoming impacted in the common bile-duct, with jaundice as the result. The worms themselves seldom produce symptoms, and unless they are actually found in the duct they could never be diagnosed with certainty as the cause of jaundice. Even if the worms or their ova were

found in the patient's faeces, it would be a bold thing to diagnose that an ascaris impacted in the bile-duct was the cause of the jaundice.

B. Causes affecting the Wall of the Duct.

Catarrh of the Mucous Membrane of the Bile-duct (catarrhal jaundice).—This is a common cause of jaundice in young people the most common of all. It is supposed to be due to the obstruction caused by the swelling of the mucous membrane, and it is almost impossible to distinguish clinically between cases in which the catarrh is confined to the bile-ducts and those in which it began in the duodenum and thence extended to the biliary papilla. It is usually preceded by gastro-intestinal disturbances, especially epigastric discomfort and dyspepsia. The jaundice develops almost suddenly in many cases, and it may become intense, the stools being clay-coloured and the urine dark with bile pigment. There may be a slight rise of temperature at first, the pulse may be less accelerated than would be proportionate to the temperature, and in quite rare cases it is absolutely slowed down to 40, or even 30: the liver and spleen may be enlarged slightly, the tongue furred, and the breath foul: loss of appetite, nausea, constipation, a feeling of weight and discomfort in the right hypochondriac region may also be prominent symptoms. In mild cases the jaundice is slight and disappears at the end of one, two, or three weeks: sometimes it lasts as long as eight weeks, or even more. In considering the diagnosis, it should be remembered that jaundice in a child or a young adult is most likely to be due to catarrh. The slightness of the pain helps to exclude gall-stones and chronic pancreatitis, and malignant disease is rendered improbable should the jaundice presently clear up, and if the patient does not emaciate. There is a growing belief that so-called catarrhal jaundice is really a specific infectious fever allied to the exanthemata, and many instances of its affecting several members of a family or school or village within a short period of one another are on record. It is, moreover, quite uncommon for a patient to have a second attack later on in life.

Catarrh of the Pancreatic Ducts, extending to the ampulla of Vater and so to the bile-ducts, has already been discussed under *chronic pancreatitis* above. It differs from catarrh starting in the duodenum or in the bile-duct by being associated with periodic attacks of colicky epigastric pain resembling gall-stone colic.

Cicatriziation following Ulceration of the Duct.—Simple fibrous stricture of the bile-ducts is a possible but rare result of ulceration due to gall-stones. If the cystic duct is thus stenosed, distention of the gall-bladder without jaundice follows: if the hepatic duct, jaundice and enlargement of the liver without distention of the gall-bladder: and if the common duct, intense jaundice, enlargement of the liver, and possibly, but not necessarily, distention of the gall-bladder. It is practically impossible to diagnose between this condition and impacted gall-stones during life, except by laparotomy.

Congenital Obliteration of the Bile-ducts. Jaundice in infants is almost always transient, *icterus neonatorum* developing about the third day and passing off in a week or less. If an infant should remain persistently jaundiced, a grave condition is almost certainly present, though only laparotomy or a post-mortem examination, as a rule, can decide whether it is due to congenital syphilis with or without cirrhosis and pervious ducts, to congenital obliteration of the bile-ducts, or to '*icterus gravis*': the last term being used when the child dies and no obvious cause for the jaundice can be found post mortem. As regards congenital obliteration of the bile-ducts, boys are affected more frequently than girls. Jaundice may be present at birth or appear on the second day, or even as late as the fourteenth day. At first it is slight, but soon becomes intense. Constipation, pale motions, bile in the urine, and spontaneous hæmorrhages especially from the umbilicus are the most prominent symptoms. Death may take place in two or three weeks when hæmorrhage occurs, but if there is no bleeding life may be prolonged for six or seven months. Increasing jaundice, colourless motions, bile-stained urine, and spontaneous hæmorrhages would point to some condition more serious than *icterus neonatorum*.

C. Causes Compressing the Duct from Outside or Invading it from Outside.

When *compression* of the common bile-duct is spoken of, the term *invasion* of it would often be more correct, especially when the so-called compression is due to secondary deposits of malignant disease in the lymphatic glands in the portal fissure. In almost all

cases of the kind jaundice is persistent, and it is often progressive, although there may be slight variations in its depth.

Secondary Malignant Glands.—The lymphatic glands in the portal fissure are very liable to become enlarged from deposits of secondary growth in cases of abdominal malignant disease. Jaundice with or without ascites is a prominent indication of such a condition, and when both jaundice and ascites are present in a case of malignant disease of the stomach or intestine, whether the liver is enlarged or not, it is probable that there are enlarged malignant glands in the portal fissure. The difficulty of diagnosis arises in cases in which no primary growth can be found. In a fair number of these it is in the rectum, colon, ovary, or pancreas.

Lymphadenomatous Glands.—The portal glands occasionally become enlarged in cases of lymphadenoma (Hodgkin's disease), or lymphosarcoma, with a similar result. The presence of enlarged superficial lymph glands and enlargement of the spleen and liver, together with a simple anaemia without leucocytosis, would suggest this diagnosis. In most cases of lymphadenoma in which jaundice occurs it is a late symptom, arising long after the correct diagnosis has already been made.

Tuberculous Glands.—Although the glands in the portal fissure frequently become caseous in cases of tuberculous peritonitis, they rarely compress the bile-duct and cause jaundice.

Lymphatic Leukæmic Glands.—The visceral glands may become enormously enlarged in some cases of lymphatic leukemia, and in rare instances those in the portal fissure have led to jaundice. The diagnosis is easy, even if the spleen and superficial lymphatic glands are not enlarged, for a blood-count would show that the total number of leucocytes per c.mm. of blood was raised to anything between 50,000 and 1,000,000, whilst the differential leucocyte count would show a great preponderance of lymphocytes.

Tumours of the Liver. Any disease which causes a local enlargement of the liver, e.g., carcinoma, sarcoma, abscess, gumma, actinomycosis, or hydatid, in the immediate neighbourhood of the portal fissure, may compress the common bile-duct and lead to jaundice, and if the portal vein is compressed at the same time, as it is apt to be, there will be ascites too. In many such cases, however, the jaundice is really due to deposits in the portal lymphatic glands rather than to the lumps in the liver itself, for if the glands escape there may be numbers of malignant deposits in the liver without any jaundice at all.

Tumours of the Pancreas.—A tumour of the head of the pancreas generally causes jaundice by invading the orifice of the common bile-duct. In some cases, situated far back in the abdomen, a mass can be felt which on account of its close proximity to the aorta, may present distinct transmitted pulsation. It may prove difficult, without artificially inflating the stomach, to distinguish it from a tumour of the latter or of the liver. A pancreatic tumour is situated behind the stomach, and does not, as a rule, move on respiration, though if attached to the portal fissure it moves with the liver. Glycosuria and fatty stools would be evidence in favour of a pancreatic tumour, even if no tumour were palpable. The tests

described on pp. 129–30 could be employed here too. The gall-bladder is apt to become distended; indeed, persistent and increasing jaundice and decided enlargement of

the gall-bladder in a person of the cancer age are probably the most characteristic symptoms of carcinoma of the head of the pancreas.

Tumours of the Duodenum. Primary carcinoma of the duodenum is very rare, but when it does occur it usually arises in the immediate neighbourhood of the biliary papilla, and by obstructing the common bile-duct causes persistent jaundice, with progressive emaciation. Duodenal ulcer with periduodenal adhesions may form a mass simulating cancer, and jaundice may be present at the same time if the bile-duct is involved; simple ulceration of the duodenum, however, is much commoner in the first part of the duodenum than it is as far along as the opening of the bile-duct.

Tumours of the Stomach. A carcinomatous tumour of the pyloric end of the stomach may become adherent to the portal fissure and cause jaundice by compressing the common bile-duct. If, however, the existence of a gastric carcinoma were known in a patient who developed jaundice, the chances would be strongly in favour of the latter being due to obstruction, not by the primary growth, but by secondary deposits in the portal lymph-glands. It should also be borne in mind, however, that even when carcinoma exists, a microbial catarrh of the duodenum may cause transient non-malignant jaundice.

Tumours of the Colon.—Carcinoma of the hepatic flexure or transverse colon may become adherent to the liver and cause jaundice by compressing the common bile-duct. It may be difficult to distinguish such a tumour from a local enlargement of the liver; but constipation, vomiting, tympanitic distention of the intestine, and the passage of blood per rectum would point to a growth in the colon. In most of such cases, however, the obstruction to the bile-ducts is not by the primary growth, but by secondary deposits in the portal glands. The importance of rectal examination has already been insisted on, whilst much help in diagnosis may also be afforded by serial X-ray examination of the alimentary canal after a bismuth or barium meal.

Tumours of the Right Kidney.—Large tumours of the right kidney, especially malignant growths, may compress the bile-duct and cause jaundice. If the tumour becomes adherent to the liver it is difficult to distinguish it from an enlargement of that organ, as the liver and the enlarged kidney would move together during respiration. If the abdomen is palpated bimanually, however, the loin may be felt to be filled out behind; and, in front, the edge of the liver may be distinguished lying over the front of the tumour, and it may be possible to detect a vertical band of colonic resonance over the otherwise dull mass. Hematuria, albuminuria, or pyuria would be additional evidence of renal disease.

Transitory attacks of slight jaundice are not uncommon in association with movable kidney. This is possibly due to compression of the common bile-duct by the kidney, but it may also result from the associated enteroptosis causing a drag on the duodenum, and a kinking of the common bile-duct. The diagnosis of movable kidney is not difficult, the position and the mobility of the tumour, and the curious sickening sensation experienced by the patient when it is compressed, being sufficiently characteristic.

Tumours of the Right Suprarenal Capsule.—Malignant growth of the right suprarenal capsule is very rare, but it may give rise to an enormous tumour difficult to distinguish from a renal, or even in some cases a hepatic, enlargement. Malignant disease of one capsule causes no symptoms of Addison's disease if the other remains healthy. In children, hypernephroma may be suggested by the premature development of pubic hair (see p. 508).

Ovarian Tumours.—A large ovarian cyst may extend upwards to the portal fissure, compress the common bile-duct, and cause jaundice, but such a complication is rare; indeed, when jaundice is associated with ovarian tumour the suspicion will naturally be that the latter is malignant and that there are secondary deposits in the glands in the portal fissure obstructing the large bile-ducts. Ascites is very apt to be present at the same time, so that unless the existence of an ovarian tumour is already known, or unless its existence can be determined by abdominal, vaginal, or rectal examination, there may be much difficulty in determining the precise cause of the jaundice, though if cirrhosis of the liver can be excluded, some form of malignant disease will probably be suspected.

Tumours of the Uterus.—A large tumour of the uterus may cause jaundice in a similar manner to an ovarian tumour, but even more rarely.

Tumours of the Omentum.—A large omental tumour may compress the bile-duct and thus cause jaundice, but it is an exceedingly rare result of such a condition. Whether malignant or tuberculous, it usually lies across the upper part of the abdomen, is superficial, and moves slightly with respiration. If it has become adherent to the liver it may be difficult to distinguish it from a local enlargement of the latter. In any case the jaundice will probably be diagnosed as due to deposits—tuberculous or malignant—in the portal glands, rather than to the omental mass itself.

Aneurysm of the Hepatic Artery, Celiac Axis, or Abdominal Aorta.—An aneurysm of the hepatic artery is decidedly rare, but it is not unheard of in cases of fungating endocarditis with embolism. Jaundice is intense, on account of the close proximity of the hepatic artery to the common bile-duct. A correct diagnosis would be almost impossible during life, especially in view of the fact that jaundice may occur in fungating endocarditis cases simply from the inspissation of the bile that results from the toxæmia and fever.

Aneurysm of the celiac axis or upper part of the abdominal aorta is also a very rare cause of jaundice. An abdominal tumour with marked expansile pulsation, a systolic bruit, and abdominal pain, are the most important diagnostic signs, especially if they occur in a person who is known to have had syphilis.

II. JAUNDICE WITHOUT OBSTRUCTION OF THE LARGER BILE-DUCTS.

It may sometimes be next to impossible to decide upon clinical grounds alone whether, in a particular case, jaundice is due to obstruction to the main bile-ducts by such things as carcinoma, catarrh, or gall-stones on the one hand, or to non-obstructive causes, such as hæmolysis or derangement of the functions of the liver cells, upon the other. It is held that *van den Bergh's test* is of material help in deciding between the two groups, though the reaction is too recent for us to be certain as to its value in differential diagnosis. Broadly speaking, the test consists in applying Ehrlich's diazo-reaction to the patient's blood serum. The latter is obtained by venepuncture, about 3 c.c. of blood sufficing; it is centrifuged, or, alternatively, the serum is pipetted off after clotting has occurred and the clot has separated from the serum. To 1 c.c. of the latter 1 c.c. of freshly mixed diazo reagent (p. 217) is added in a small test-tube, when, if the jaundice be obstructive, a bluish-violet coloration occurs within 10 to 20 seconds; should there be no development of this colour forthwith, but a delayed reaction with the formation of first a reddish tint in a minute or more, deepening gradually during fifteen minutes or longer to a violet shade, the jaundice is non-obstructive according to van den Bergh.

The following varieties of non-obstructive jaundice may be discussed *seriatim* :—

A. Causes associated with Disease of the Liver.

Carcinoma of the Liver.—Jaundice occurs in more than 50 per cent of the cases of malignant disease of the liver, whether secondary or primary; it is seldom, however, that the masses in the liver itself cause the jaundice, but rather the associated deposits in the portal glands. A liver may contain hundreds of nodules of new growth without there being either jaundice or ascites if the portal glands escape. Jaundice brought about in this manner is permanent, and when the common duct is involved is intense. The skin, which at first is a deep orange, becomes greenish, and finally the dark olive-green tint which is almost pathognomonic of jaundice due to malignant disease. Increasing jaundice in a patient over 40 years of age, who has been ill less than six months, who has progressively wasted and become weaker, and whose liver is enormously enlarged, hard, and nodular, points without much doubt to malignant disease, though careful search may be required before the primary source is found. The nodules may even be felt to be umbilicated. Primary carcinoma of the liver should not be diagnosed until a very careful physical examination has failed to furnish evidence of the primary growth in some other organ.

Cirrhosis.—In many cases of cirrhosis of the liver the late or multilobular stage of the disease may be reached without there having been any jaundice at all. If it occurs late in the disease, when ascites is already present, the jaundice is usually slight. Ascites is the most constant and characteristic feature at this late stage of cirrhosis, but when slight jaundice and ascites are associated in a patient who gives a definite history of alcoholism, and also has symptoms and shows signs of this condition (p. 881), and has a hard liver with a well defined and beaded edge, the diagnosis of cirrhosis of the liver is not difficult. Sometimes, however, jaundice is a marked feature of the case at an early stage, when the organ is still small and the fibrosis unilobular, and at this time ascites is conspicuous by its absence. There is often an evening rise of temperature to about 100° F. (*Fig. 66*, p. 47). The liver is considerably enlarged, its surface is smooth, firm perhaps, and tender, and its edge is even and well defined, reaching below the ribs perhaps to the level of the umbilicus or even below it. The jaundice may pass off, and the patient survive many years before the multilobular ascitic stage of his malady is reached; on the other hand, if the jaundice persists and deepens, the prognosis is grave; cholemia sets in, drowsiness and muttering delirium passing on to coma and death.

There is a peculiar form of *cirrhosis of the liver* (*Hanot's*) which affects several members of the same family, and whose first symptom in each patient is jaundice. The disease appears not to be caused by alcohol, syphilis, or malaria, though there is sometimes a positive Wassermann reaction suggestive of congenital syphilis. The patient may live many years with more or less jaundice all the time. The icteric tinge of the skin is often unaccompanied by bile pigment in the urine in these chronic cases—a variety of acholuric jaundice. The liver and spleen are both enlarged and hard; sooner or later ascites supervenes, and the patient dies in the same kind of way as an alcoholic cirrhotic does.

Although the malady is apt to affect brothers and sisters of the same family, there are sporadic individual cases in which one child only in the family may be affected. Clubbed fingers are apt to be associated with the condition.

There is another malady, known as *familial acholuric jaundice*, which simulates Hanot's cirrhosis very closely during life, but is found at operation to present no hepatic cirrhosis. Several members of the same family are affected, the spleen is enlarged considerably, the symptoms develop either soon after birth or during the first ten years of life, progress slowly, with periods of remission, and during exacerbations there is considerable chlorotic anemia, associated with fragility of the red corpuscles as tested with varying strengths of salt solution, and a tendency to hæmorrhages—hamatemesis, hæmoptysis, epistaxis, and purpura in particular. The pathology of this condition is still obscure; some of the cases give a positive Wassermann test and appear to be due to congenital syphilis; these are differentiated by some observers from others which they term true familial acholuric jaundice, where the Wassermann test is negative. Excision of the spleen has cured not a few of these cases, both of the positive and of the negative Wassermann reaction types.

There is yet another variety of cirrhosis of the liver which occurs in children and young people, characterized by enormous enlargement of the spleen, slight enlargement of the liver, anemia without leucocytosis, hamatemesis, clubbing of the fingers, jaundice, and stunted growth. It differs from Hanot's cirrhosis in that the liver is smaller and the spleen larger, and from the latter feature of the case it is termed *splenomegalic cirrhosis*. Whether or not Hanot's cirrhosis, familial acholuric jaundice, and splenomegalic cirrhosis are distinct diseases, or merely different types of the same disease, or, alternatively, different and variable types of apparently similar but really different diseases, we are not yet in a position to say. It may be that familial acholuric jaundice cases are early stages, not yet cirrhotic, of a malady which later on would be cirrhosis of the liver of Hanot's or the splenomegalic type—just as splenic anemia, if watched for years, is often found to develop into Banti's disease with cirrhosis of the liver and ascites. Knowledge at present is too imperfect, therefore, to enable us to lay down any firm rules by which to decide what name to give to particular instances of this type of jaundice case, though the group as a whole may generally be recognized with ease.

Single or Tropical Abscess. In cases of single or tropical abscess of the liver intense jaundice is rare, and it is likely to occur only when the abscess bulges in the region of the portal fissure. The general appearance of a patient who is suffering from hepatic abscess may, however, be mistaken for jaundice, because the complexion is sallow, and the conjunctiva may even have a slightly icteroid tinge. The urine, however, seldom contains bile pigment. The disease mostly affects people who have resided in the tropics, particularly those who have had dysentery. The diagnosis is discussed on p. 161. Should the abscess open into the lung, the dull reddish pus expectorated would point to its origin in the liver even though no *Amaba dysenteriae* were found in the pus.

Multiple Abscesses in the Liver might theoretically arise by infection through any one of four different channels, namely, the portal vein, the bile-ducts, the hepatic artery, or the lymphatics. In practice only the first two are important, giving rise to *suppurative pylophlebitis* and *suppurative cholangitis* respectively. There are really no sharp lines of demarcation between non-suppurative and suppurative inflammations of these channels; there are all intermediate stages between simple catarrh of the ducts and acute suppurative cholangitis; and there are similar degrees of inflammation in the case of the portal venules. Jaundice is almost constantly a symptom of cholangitis, and the diagnosis is arrived at when a cause for cholangitis exists, such as gall-stones, carcinoma of the gall-bladder, empyema of the gall-bladder after typhoid fever, and when the patient's liver enlarges and becomes tender, especially if rigors also occur from time to time. Suppurative pylophlebitis is diagnosed less easily, and indeed it is often overlooked as a cause for an obscure febrile illness accompanied by rigors. About half the patients who have it develop jaundice, and in over half the cases the cause of the infection of the portal vein is appendicitis. If, therefore, a patient who has recently had an operation for the latter thereafter begins to do badly, developing pyrexia and rigors without apparent cause, and if that patient in the course of a week or so develops a tinge of jaundice and an enlarging, tender liver, the grave diagnosis of infective pylophlebitis should suggest itself.

In *Acute Yellow Atrophy of the Liver* jaundice is one of the earliest symptoms. In the early stages bile pigment may be found in the urine, but towards the end, when the skin becomes green, Gmelin's reaction cannot be obtained, or only a trace of pigment can be detected (acholuric jaundice).

The disease is rare. It affects females under 30 years of age more frequently than males, and in a good many cases has been preceded by fright, severe mental emotion, or child-birth. It usually commences in the same manner as an attack of catarrhal jaundice, with nausea, vomiting, loss of appetite, constipation, and pain in the right hypochondrium. At the end of two or three weeks a sudden change occurs, which commences with severe vomiting, headache, and restlessness, followed by delirium, convulsions, and coma. The temperature rises to 101° F. or 102° F., and the pulse becomes rapid. The tongue is dry and brown. There is a tendency to hæmorrhage from various parts, e.g., epistaxis, hæmatemesis, melæna, metrorrhagia. The most important diagnostic signs are the remarkable diminution of urea and uric acid, and the presence of leucin and tyrosin (*Fig. 326*) in the urine: also the rapid diminution in the extent of the hepatic dullness which takes place after the development of the above-mentioned nervous symptoms. The duration of the malady, in the majority of cases, is under fourteen days from the time of the sudden change in the type of the jaundice.

Fig. 326. Leucin (A) and tyrosin (B) crystals, as seen under the high power of the microscope.

The striking resemblance between this disease and that producible by poisons such as trinitrotoluol or tetrachlorethane suggests that acute yellow atrophy of the liver is not a single disease, but is rather a state of affairs that may result from various conditions—microbic or chemical—capable of causing acute degenerative changes in the liver cells. Some cases seem to be due to the effects of acute streptococcal septicæmia; others may be due to other forms of microbic invasion; a condition which resembles acute yellow atrophy very closely in its clinical features has affected not a few persons engaged in the varnishing of the wings of aeroplanes, or occupied upon the premises in which this work is being carried on. The varnish used is composed of acetate

of cellulose dissolved in a mixture of spirit, acetone, benzol, and tetrachlorethane (tetrachloride of ethane or acetylene tetrachloride). It is the vapour of the latter which is the cause of the toxic symptoms; in milder cases recovery occurs when the patient is removed from the works on account of continued ill-health with more or less severe gastro-intestinal symptoms—especially flatulent dyspepsia, vomiting, epigastric pains, and loss of appetite; those who remain exposed to the vapour for weeks or months develop jaundice in addition, at first exactly like a simple catarrhal jaundice, but soon passing on to a serious and generally fatal stage precisely similar to that of acute yellow atrophy of the liver, though generally without leucin and tyrosin in the urine. A somewhat similar condition results from the continued effects of *dinitrobenzene*, *trinitrotoluol* (T.N.T.), *picric acid* (trinitrophenol), and *dinitrophenol*, used in the manufacture of high explosives; and from the use of *chloride of sulphur* by rubber workers. The diagnosis is suggested by the circumstances of the occupation. Post mortem the liver in these cases is shrunken and discoloured, just as it is in acute yellow atrophy.

Chloroform anaesthesia has been followed in some cases by jaundice, as part of delayed chloroform poisoning. The symptoms may not supervene for a day or even two days after the administration of the anaesthetic; vomiting, prostration, and the development of acidosis precede the jaundice, the latter appearing in but a minority even of the fatal cases. Post mortem one finds intense degeneration of the hepatic cells, with great excess of fat globules in them as well as in the muscle fibres of the heart and in the parenchymatous cells of the kidneys.

Passive Congestion (nutmeg liver).—Jaundice occurs in severe cases of passive

congestion, especially as the result of long-standing mitral stenosis, or of fibrosis of the lung with ultimate failure of the right side of the heart. Usually there is but an icteric tinge of the conjunctivæ, but when the jaundice is more severe its association with cyanosis gives a curious dusky-green tint to the skin, especially that of the face. Œdema of the legs and ascites are also present as a rule. The liver is enlarged considerably, its edge sharp and well defined, its surface smooth, firm, tender, and possibly pulsating. Jaundice from this cause should not be difficult to diagnose. If in a chronic heart case there are both pyrexia and jaundice, fungating endocarditis is probable.

Syphilis. Congenital syphilis may cause jaundice in infants or young children as the result of intralobular fibrosis, but it is possible for the latter to be extensive without there being any jaundice, and even where the latter is present it is usually slight. If associated with uniform enlargement of the liver, wasting, and other signs of congenital syphilis, the diagnosis is not difficult.

In an adult it is possible for gummata to cause jaundice by compressing the ducts, but this is distinctly rare. The local enlargement of the liver and pyrexia may lead to a diagnosis of abscess or of secondary carcinoma. A careful examination must be made for signs of syphilis: in some cases it is not until antisyphilitic remedies have been administered and the effect watched that a correct diagnosis can be made. If there are any active lesions of the skin or mucous membranes, it may be possible to detect the *Spirochaeta pallida* microscopically: or the patient's serum may give a positive Wassermann's reaction.

Probably the commonest period at which syphilis is directly responsible for jaundice is the secondary stage, when parenchymatous degenerations are apt to occur not only in the liver with jaundice, but also in other organs, e.g., in the kidneys, with albuminuria. The symptoms may simulate those of simple catarrhal jaundice unless there are the additional guides of the roseola, sore throat, pyrexia, albuminuria, generalized lymphatic-gland enlargement, scalp tenderness, and other signs of secondary syphilis.

Active Congestion. Active congestion of the liver is not an uncommon result of many of the acute fevers, such as malaria or dysentery, particularly in Europeans in the tropics. The liver becomes enlarged and tender. The chief symptoms are slight jaundice, pain, and a feeling of fullness, weight, and oppression in the right hypochondrium, which sensations are much increased by pressure: also pain in the right shoulder, a bitter taste in the mouth, nausea, sickness, a furred tongue with indented edges, constipation, and scanty high-coloured urine. There may be a temperature of 102° F. or more, and care is needed to distinguish the state of affairs from hepatic abscess. An absence of leucocytosis would be in favour of congestion and against suppuration, though the leucocytes may be increased in both. Examination of blood-films may demonstrate the presence of malaria parasites, or on the other hand dysenteric amebæ may be found in the stools: or the diagnosis may be suggested by the beneficial effects of quinine if the condition is malarial, or of injections of emetine hydrochloride if the cause is amebic dysentery.

B. Jaundice in Acute Fevers.

Malaria. Slight jaundice may occur in long-continued tertian and æstivo-autumnal infections, and on account of the associated irregular pyrexia it may lead to a mistaken diagnosis of hepatic abscess. Discovery of the characteristic parasites in the red blood-corpuscles in blood-films (Figs. 57-60, pp. 40, 41) is the most conclusive evidence of malaria. Jaundice may also occur as a result of malarial cirrhosis. The parasites disappear rapidly from the blood when quinine has been administered recently, so that films should be taken before quinine is given, and if possible at the very start of an ague fit, at which time the hæmatozoa are at their most typical stage of development. If quinine has been given already, however, presumptive evidence of malaria exists if there is no leucocytosis, if the differential leucocyte count shows a decided increase in the proportion of large hyaline lymphocytes—up to 15 per cent or more—and if the urine exhibits temporary urobilinuria.

Typhus Fever. Jaundice may occur occasionally in this disease, which, fortunately, is now extremely rare in Great Britain, though it may reappear in any country during times of famine or distress. It is a disease of "poverty, famine, dirt, and squalor": spread by bugs and lice: and is known by various names, including 'gaol fever' and 'spotted fever'. The onset is more sudden, and the prostration occurs earlier and is more marked, than in typhoid fever. There is often a slight leucocytosis, whereas in typhoid fever

there is none. The rash appears from the third to the fifth day, and consists of a dusky red mottling—the mulberry rash—rose-coloured papules which appear on the abdomen

Fig. 327. Typhus eruption on front of trunk. Note that in addition to simple red spots there are also here and there brighter red purpuric spots and duller purplish brown spots which are described as the subcutaneous mottling of typhus. In typhoid fever there are rose spots only, without the purpuric spots and without the dull subcutaneous mottling.

Skutta Árpád, Budapest.

and chest (*Fig. 327*), together with a certain number of petechiae—the latter not being found in typhoid cases. The fever tends to terminate by crisis rather than by lysis (*Fig. 614*, p. 786). Widal's reaction is negative.

Typhoid Fever. Jaundice is rare in this disease; it occurred in only three out of Osler's series of 829 cases. It may be due to an inflammation of the bile passages by typhoid bacilli, or may result from destructive parenchymatous changes in the liver itself, or again may be carried by intravascular hemolysis; the gall-bladder may become enlarged, tender, and palpable, though this may also occur in typhoid fever without any jaundice at all. This may arise occasionally as a complication in the course of the disease, or it may be a sequela, or again it may be an early and prominent symptom for which the patient seeks advice. Cases have been recorded of primary typhoid infection of the gall-bladder and bile-ducts without any accompanying ulceration of the intestine. The low pulse ratio when compared with the temperature, e.g., a pulse of 90 with a temperature of 104° F., the presence of typical rose-red spots on the abdomen, enlargement of the spleen, leucopenia, and a positive Widal's reaction either to Eberth's bacillus or to *Bacillus paratyphosus A* or to *Bacillus paratyphosus B*, are the most important signs which would point to a diagnosis of typhoid or paratyphoid fever.

Pyæmia and Septicæmia. Jaundice is frequently a late symptom of pyæmia, quite apart from the presence of multiple abscesses in the liver due to portal or arterial pyæmia. Rigors, high irregular temperature, rapid pulse, profuse sweating, rapid emaciation, and progressive loss of strength are symptoms which, if developing after parturition, wounds, or operations, would point without much doubt to a diagnosis of pyæmia or septicæmia; and the causal organism may be recoverable on blood-culture. In some instances of acute septicæmia due to streptococci, staphylococci, and perhaps other micro-organisms, there has been intense jaundice of the skin and conjunctivæ of a peculiar mustard-yellow tint, without the urine giving a positive Gmelin's test. The urine may or may not be discoloured; in some instances it looks merely concentrated, in others almost like porter, yet with no play of colours to the nitric acid test, owing partly at least to the degree to which the bile pigments have been oxidized already before they reach the urine. This acholuric jaundice in septic cases is remarkable, and may be confusing. In some cases it would seem to depend on acute degenerative changes in the hepatic parenchyma, but in others it is regarded as being due to acute destruction of the blood pigment in the general circulation—'hemolytic jaundice', as distinct from hepatic jaundice—a condition which may occur in pernicious anemia too, when the blood serum is tinged yellow with bile pigments though the urine contains none.

Influenza in its ordinary mild forms rarely causes jaundice; but in times of severe epidemic, when virulent types of influenzo-pneumococcal or influenzo-streptococcal septicæmia are familiar and fatal, jaundice is met with in a small percentage of cases.

Pneumonia. Jaundice occurs occasionally as a complication of pneumonia. It varies very much in its frequency in different epidemics of the disease, and is rarely intense. It is probably due to engorgement of the liver and catarrh of the bile-ducts. Its more frequent association with right basal pneumonia is suggestive. The sudden onset with a rigor, the high temperature, the rapid respiration-rate, which is above the ordinary temperature and respiration ratio, and the comparatively slow pulse (e.g., T. 104° F., R. 40, P. 100), the characteristic tenacious, russet-brown sputum, the short catchy cough, the pain in the side, the pleuritic rub, and the signs of consolidation of the lung, the hot dry skin, the deficiency of chlorides in the urine, and the occurrence of herpes facialis, are the accompanying indications which in the majority of cases would point to a diagnosis of pneumonia.

Weil's Disease, as it used to be called, or *spirochaetosis icterohæmorrhagica* which is the more scientific name for at least one well-defined variety of Weil's disease, is characterized by a sudden onset with pyrexia, severe pain in the back and limbs, headache, and giddiness, followed in two to four days by jaundice, enlargement of the liver and spleen, and nephritis. The jaundice becomes intense within twenty-four hours, the temperature rises to 103° to 104° F., and the pulse becomes rapid, though, as in typhoid fever, it is often relatively slow in relation to the degree of pyrexia, being about 100 per minute, for instance, with a temperature of 104° F. In a typical case the pyrexia has two stages—initial and secondary; that is to say, after a few days or a week of relatively high fever there may be a gradual fall by lysis, and then during the third week or thereabouts a secondary rise, or relapse, with a second fall to normal by lysis, and without the same severity of symptoms as those of the primary pyrexia. With this type of pyrexia and jaundice the patient may present a degree of herpes facialis which might almost be described as terrific herpes, which

may spread from oral and nasal regions to cheeks and neck, become hemorrhagic, septic, crusty, and alarming. There is generally albuminuria, and sometimes definite nephritis with hematuria and tube-casts. The lungs present catarrhal signs, seldom amounting to pneumonia; there is liability to severe hemorrhage—purpura, hæmoptysis, hæmatemesis, epistaxis, and melæna in particular; there is infection of the conjunctivæ, tenderness of the eyeballs, and liability to stupor, coma, convulsions, and death. The diagnosis may be suggested by the clinical condition, but it is clinched by finding the causal spirochæte in the patient's blood or urine, or more certainly by injecting the patient's blood or urine during the first week into guinea-pigs, and recovering the spirochæte from the blood, tissues, or urine of the latter. After the first week the patient's blood ceases to be of use for guinea-pig inoculations, though the urine may be employed for a longer period, even up to four weeks.

Epidemic Catarrhal or Infective Jaundice is similar in some respects to simple catarrhal jaundice, but differs in its really epidemic character and in its liability to a fatal ending. It is met with in Eastern subtropical countries, notably Mesopotamia. It is clearly of microbial causation, but there are doubts as to its essential bacteriology. There is generally a history of some diarrhœa or gastro-intestinal disturbance for days or weeks, and then a more acute phase sets in with mild pyrexia, chilliness or rigor, pains all over, discomfort in the upper abdomen, and, three or four days later, jaundice, deepening for a variable number of days and then gradually subsiding as in catarrhal jaundice, except in the fatal cases, in which stupor, coma, convulsions, and hyperpyrexia precede death. In average cases the nervous symptoms are mild; the liver and spleen both enlarge slightly, and they may be tender; the pyrexia lasts from five to ten days, and there is gradual recovery. The pulse-rate may be quite slow—50, for instance, with a temperature of 101° F. The diagnosis depends mainly on the epidemic circumstances; there is no simple bacteriological or blood test for distinguishing a sporadic case.

Yellow Fever in some respects resembles acute yellow atrophy of the liver, but the liver does not atrophy, neither does the spleen enlarge, and crystals of leucin and tyrosin are not found in the urine. It is essentially a tropical or subtropical disease, prevalent in the West Indies and Central and South America. The incubation period is from three to four days, and the onset sudden, with rigors, headache, pain in the back and limbs, and constipation. Jaundice is an early symptom, and one of the most characteristic, but it varies in intensity, being much more severe in fatal than in mild cases. The temperature rises to 102° or 105° F.; the pulse is rapid at first, but may fall as the temperature rises, and this is regarded as a very typical sign of the disease. Albuminuria, black vomit, hemorrhage from the gums and beneath the skin are other important symptoms. A sporadic case occurring in this country would probably be looked upon as acute yellow atrophy of the liver unless a definite history of exposure to infection were obtainable. It may be difficult to distinguish it from dengue (p. 571) and pernicious malaria. From the latter it can be diagnosed if crescents are discovered in the blood (Figs. 59, 60).

Spiking Fever. Jaundice is a common symptom of this contagious fever, which is prevalent in India, and is liable to arise in other countries in times of famine. It is spread by blood-bugs. Considerable enlargement of the liver and spleen, and a good deal of abdominal pain and tenderness, are present in most cases; also epistaxis and hæmatemesis. The most characteristic feature of the disease is the temperature, which rises abruptly to 104° or 105°, and even to 108° F., remains high for five or six days, and then suddenly falls to normal, when, after an interval of about a week, it again rises and remains high for three or four days (Fig. 48, p. 36), to relapse again even more than once in a similar way thereafter. During the periods of pyrexia the *Spirochæta obermeieri* (Fig. 636, p. 779) may be found on examining blood-films prepared and stained in the same manner as for the detection of malaria parasites. The blood examination serves to distinguish it from malaria.

There are numerous other forms of fever and microbial infection—rheumatic fever, for example, measles, dental sepsis, trench fever, pyrexial phthisis, and so forth—in which jaundice occurs occasionally; but the event is rare, and the diagnosis is to be made upon the other features of the case.

C. Jaundice due to Poisons.

Phosphorus.—Jaundice, though by no means constant, is one of the most characteristic symptoms of phosphorus poisoning. It is slight at first, appearing on the second or third

day in severe cases, but in mild ones not until the end of the first week, or even later. This form of poisoning has become rare since the stringent law regulating the manufacture of matches from the non-poisonous form of phosphorus has been in force. In the cases which do occur the phosphorus has generally been taken in the form of match-heads or rat paste, with suicidal intent. At first the signs are those of acute irritant poisoning, coming on soon after the phosphorus has been swallowed, viz.: nausea, vomiting, severe burning pains in the epigastrium, collapse, extreme thirst, rapid feeble pulse, rapid respiration, and tenderness in the epigastrium and right hypochondriac regions. In many cases that receive treatment early these acute irritant symptoms subside in a day or two, and recovery results. If they do not thus subside, however, after from two to five days, the symptoms change, the vomit becomes black or brownish from the presence of blood, jaundice appears and deepens rapidly, the liver enlarges, and headache, drowsiness, delirium, convulsions, and coma supervene, followed shortly by death. If hepatic enlargement cannot be ascertained it may be difficult to distinguish phosphorus poisoning from acute yellow atrophy of the liver. Hemorrhages, although common, are not as frequent as in acute yellow atrophy. The urine is concentrated and strongly acid: the total nitrogen is first reduced, as in cases of starvation, to about one-fourth the usual, and then, in spite of the fact that the patient can retain no food, it rises to the usual amount. Urea forms the greater part of the total nitrogen, but towards the end the total amount of ammonia is increased. Leucin and tyrosin are not usually found, and the chlorides are diminished. The condition of the urine, therefore, forms a contrast to the changes which are found in cases of acute yellow atrophy. The chief indications of the disease that are found post mortem are jaundice, multiple punctiform hemorrhages, fatty degeneration of the liver, kidneys, and heart, and enlargement of the spleen.

Phosphuretted Hydrogen is an intensely poisonous gas, generally inhaled accidentally in trade processes. Cases occur sometimes in seamen concerned in shipping ferro-silicon, a substance employed in steel-hardening works. It contains as impurities both phosphide of calcium and arsenide of calcium: and if the ferro-silicon becomes damp in an enclosed space, such as the hold of a ship, the resultant fumes of phosphuretted and arseniuretted hydrogen may poison those who may be sleeping near the ship's hold or other similar place. The symptoms come on acutely with weakness, dizziness, inability to walk or stand; vomiting: abdominal pains: a pallor which develops rapidly on account of the intense blood destruction: hemorrhages, particularly hamatemesis, melena, and petechiae in the skin, or purpura: followed, if the patient survives long enough, by jaundice, delusions, delirium, coma, and death.

Arсениuretted Hydrogen and *Antimoniuretted Hydrogen* cause jaundice in a manner similar to phosphuretted hydrogen through blood destruction and extreme concentration of the bile: the gases may be inhaled in the course of work in the chemical laboratory, or under certain trade conditions in which, for example, hydrogen is being prepared from impure iron ores by the action of hydrochloric acid, as in the filling of balloons. *Seleniuretted Hydrogen* poisoning is also similar, though rare and generally less severe: it has occurred in work connected with special paints, such as those used for the indicator needles of compasses on aeroplanes.

Male Fern poisoning (*filix mas*) has occurred when an overdose of the drug has been given to a susceptible person who is under treatment for tape worm: the jaundice that may occur is not necessarily a fatal symptom, but the patient may become extremely collapsed and ill before recovering from the effects of the drug.

Toluylenediamine has been used for experimental purposes: when injected into dogs it soon produces intense jaundice: it causes destruction of blood, and the hæmoglobin thus liberated increases the viscosity of the bile and jaundice results.

Tetrachlorethane, *Dinitrobenzene*, *Trinitrophenol*, *Dinitrophenol*, *Chloroform*, and *Chloride of Sulphur* are discussed above (p. 416). It may be noted that picric acid (trinitrophenol) has been taken by malingerers for purposes of deception, the sclerotics assuming a decided yellow tint after a dosage of between 30 and 90 centigrams.

So-called *Mushroom Poisoning* is due, not to eating true mushrooms, but poisonous fungi that have been mistaken for mushrooms. There is a long list of poisonous fungi which need not be given in detail: the symptoms caused by most of them take the form of acute intestinal disturbance, with vomiting, diarrhoea, and collapse, passing on in the

worst cases to stupor, coma with or without convulsions, and in a few cases jaundice, which results from the intense degeneration of the liver cells which the fungi poisons produce.

Snake Poison.—Jaundice is a common result of snake-bite. The diagnosis depends upon the history. The symptoms vary with the kind of snake that has bitten the patient. In England the only poisonous variety is the adder or viper, whose bite is followed almost at once by a burning local pain, quickly succeeded by acute ascending œdema and darkening discoloration of the limb. The patient is nauseated and presently vomits, he turns giddy and faint, has to lie down, and in from one to three hours is completely prostrated, often comatose, and covered with clammy perspiration. The temperature falls below normal, the pulse may be almost imperceptible, and death may result at this stage. More often the severe constitutional symptoms pass off gradually, improvement beginning within twenty-four hours; but the swelling and discoloration of the bitten limb remain extreme, and there may be generalized œdema all over the body. Suppuration or even gangrene is common, and recovery is apt to be very slow, even when appropriate surgical measures are employed at once. It is during the period between the passing off of the initial coma and the beginning of convalescence that jaundice is prone to develop.

Arsenobenzol Derivatives (salvarsan, neosalvarsan, galy, kharsivan, neokharsivan, arsenobillon, novarsenobillon, and so on) are used so extensively in the treatment of syphilis that it is fortunate that only in very exceptional cases are there untoward or fatal effects. It is common enough for the patient to vomit, have one or more rigors, with transient pyrexia during the next few hours after a dose; but these symptoms have passed off completely after a night's rest in the great majority of cases. Very occasionally, however, in a susceptible individual symptoms of a profound toxæmia may set in two or three days after, with prostration, irritability, delirium, or jaundice, and although the patient may still recover he is for the time being in great danger: these symptoms are not due to arsenical poisoning in the ordinary sense, but to acute degeneration of the hepatic cells produced by the salvarsan. Before death there may be convulsions or Cheyne-Stokes' breathing; in rare cases these symptoms, instead of coming on within four days of the injection, may be delayed for a longer interval, even up to five weeks.

D. Jaundice due to Nervous Causes.

Icterus Nervosa: Mental Emotion.—Cases are on record of jaundice following almost immediately after some violent mental emotion, especially grief, shock, or excessive anxiety, but they are of extreme rarity and their mode of causation is purely hypothetical. Jaundice may occur similarly after concussion of the brain or other effect of head injury.

E. Jaundice due to Unclassified Causes.

Icterus Neonatorum and **Icterus Gravis of Infants** are referred to on p. 411, and **Acholic** on p. 415; **Familial Jaundice** is but a type of familial acholic jaundice (p. 415).

Splenic Anæmia, although the blood serum will often be of a yellowish tint from bile pigments in it, true jaundice, recognizable clinically by the colour of the conjunctivæ, is rare; the chief danger is that pernicious anæmia may be mistaken for jaundice, especially when the urine may be of a golden-brown colour suggestive of bile in the urine—the result, not of bile pigments, but of urobilin in it. Jaundice in **Splenic Anæmia** results mainly when the latter has reached the cirrhotic stage of Banti's disease, though it may be a mere matter of opinion sometimes as to whether, in a particular case, the condition should be labelled splenic anæmia with jaundice, splenomegalic cirrhosis, Hanot's cirrhosis, or familial acholic jaundice. Some hold that undue fragility of the red corpuscles serves to put the case into one or other of the latter groups and to take it out of the splenic anæmia group, but there is no absolute certainty on the point. Jaundice in **Leukæmia** is but an incident—the diagnosis is made by the blood-count (pp. 32-35), and jaundice is rare. In **Lymphadenoma** jaundice may be due to enlarged portal glands obstructing the common bile-duct, but sometimes the disease causes non-obstructive jaundice similar to that which arises in some cases of leukæmia; the diagnosis is discussed on pp. 471, 782. **Paroxysmal Hæmoglobinuria** is rare, and is a still rarer cause of jaundice; the simulation of hæmaturia is the symptom attracting attention, and the diagnosis is discussed on p. 358.

JERK, KNEE. (See KNEE-JERK, ABNORMALITIES OF THE, p. 450.)

JOINTS, AFFECTIONS OF THE. It will be well to place these in two groups: (I) *Acute*; (II) *Chronic*.

I. ACUTE JOINT AFFECTIONS.

Arthritis due to Rheumatic Fever is the most frequent of these. The patient has often had the disease before, or other members of the family may have had it; there may be manifestations of past rheumatic affection of other parts of the body—organic mitral disease, for instance. A history of past chorea, several attacks of tonsillitis, pericarditis, or rheumatic erythema or nodules will help. The distinguishing features of the arthritis are that it is acute, and affects first and chiefly the larger joints, although in a very severe case even the joints of the hand and fingers may be implicated; it does not occur in all the affected joints simultaneously, but appears in one, a few hours after in another, and so on. As the arthritis often lasts a few days in any one joint, in some it may have passed away while others are being affected. The pain is very severe and is greatly increased by any jar of the bed; it is more fleeting than the arthritis, but, like it, flits from joint to joint, hardly ever returning to the same joint in the same attack. The swelling of the joint is usually only slight or moderate; it is due to synovial effusion, never suppurates, generally subsides in a few days, and usually in at most a fortnight the joint returns completely to its normal condition. Permanent distortion or stiffness of the joints after rheumatic fever occurs, but it is highly exceptional. Often there is a red blush over the joint when first affected.

The most important diagnostic characteristics of this arthritis are: (1) The fact that it flits from joint to joint. Never diagnose rheumatic fever so long as only one joint is affected. I have known failure to remember this lead to a diagnosis of rheumatic fever in traumatic arthritis, tuberculous arthritis, arthritis due to acute necrosis of a bone near a joint, and acute suppurative arthritis: in each of the last two the mistake has cost the patient his life. (2) The arthritis in turn quickly leaves joints. Failure to remember this has often caused septic, gonococcal and various forms of infective arthritis to be called rheumatic arthritis. The drenching, sour-smelling sweats, and the relief of the pain by salicylates, are very characteristic of rheumatic fever, but septicæmia also causes sweating. The sweating of rheumatic fever is particularly liable to be accompanied by minute glassy vesicles sudamina. The arthritis of rheumatic fever being transient, it is not accompanied by

Fig. 329. Temperature chart in a case of gonococcal arthritis of ordinary severity, to show the absence of effect of salicylates upon the pyrexia. There was mistaken at first for acute rheumatic fever.

much arthritic muscular atrophy. Rheumatic nodules are rare, but when present are almost diagnostic (Figs. 225, 226, p. 282); they are most often seen in young boys affected with rheumatic fever and heart disease; but very rarely they are met with in osteo-arthritis, and I have seen them with gonorrhœal arthritis. (3) The joint pains and the pyrexia are generally, though not absolutely invariably, relieved by salicylates within forty-eight hours (Fig. 328), whereas gonococcal arthritis (Fig. 329), gout (Fig. 330), acute rheumatoid arthritis (Fig. 331), and other acute joint affections, are not quickly influenced by salicylates in the same way.

Fig. 328. Temperature chart in a case of acute rheumatism, showing the rapid fall of temperature produced by the use of salicylates in adequate doses.

Septic Arthritis is constantly being thought to be rheumatic fever: a bad mistake, especially for the patient. In septic arthritis, it is true, several joints may be affected; but it may be one only, which it never is in rheumatic fever: further, in septic arthritis the trouble does not clear up in one joint and then pass to another: a joint once affected remains affected till the source of infection is removed: the soft tissues around are thickened and brawny, quite unlike rheumatic fever, and if the colour is altered—which is not often the case—it is dusky, and not the bright red of rheumatic fever. Suppuration often occurs in rheumatic fever, never. Whether or not suppuration takes place the joint often becomes fixed, which is excessively rare in rheumatic fever. Then, if proper search is made, the

Fig. 220.—Four-hourly temperature chart in a case of acute rheumatism. Woman, age 40, had had several previous attacks of typical rheumatism; recovered completely for the time being. Sanguis later had no effect upon the joints.

source of infection can usually be found: common places that are overlooked are the sockets of the teeth, and the vagina and uterus, but the source may be anywhere, e.g., septic arthritis may follow dilated bronchial tubes, cystitis, prostatic abscess, a boil on the skin, otorrhoea, inflammation of the nasal cavities, tonsillitis, cholecystitis, and perhaps ulceration of the intestine. Sometimes the most careful seeking fails to find the source, but the search must not be given up readily. The irregular temperature, usually hectic, the leucocytosis, sweats, and other signs of septicaemia are often a help.

Pneumococcal Arthritis is rare in adults, and nearly always exists as a complication of acute pneumonia. It may, however, be found without evidence of pneumococcal disease in any other part of the body. Pneumococcal otitis media should not be forgotten as its possible source. Generally only one joint is affected, usually the knee, less often some other large joint, such as the shoulder or elbow. Often there is a history of recent injury to the part. The patient suddenly feels a pain in the joint: within a few hours of this the temperature is raised; the joint swells rapidly, is very painful and exquisitely tender; yellowish-green pus is found if the joint is needled. The diagnosis is obviously easy if the patient has pneumonia, but may be difficult if he has not: it is important to come to a diagnosis early, for it is a serious disease, and if allowed to go far without incision and drainage the patient may succumb to a general septicaemia. Pneumococcal arthritis is the commonest form of infective arthritis in children under five years old. As in adults, it is confined generally to one large joint. The swelling may be very great, and extend into the soft tissues beyond the joint. The pain is less than in adults, and redness is not so marked. Its possible presence must be remembered, for as in adults, so in children, it is necessary to drain the joint early. The child has a raised temperature, and looks much more ill than does a rheumatic case.

Typhoid Arthritis. There are two varieties, both very rare: (1) That which precedes the typhoid fever: this is multiple arthritis, not of severe degree, which subsides just before definite symptoms of typhoid show themselves. It is impossible to diagnose it until the appearance of the typhoid fever. (2) This occurs during the typhoid fever: one or many joints may be affected: the arthritis is of varying severity: it may subside completely, or require incision and drainage. In a few cases even when there has been no arthritis during or before the attack of typhoid fever some chronic arthritis may appear later: most often the joints and ligaments of the spine are affected, and during the convalescence from his fever the patient complains of much pain and stiffness of his back: he is then said to have a *typhoid spine*. In a similar way the hip may become stiff, and very rarely there is chronic osteitis of the head and neck of the femur.

Scarlatinal Arthritis affects many joints, is not severe, soon subsides, and is easily diagnosed when there has been recent scarlet fever. It is commonly known as scarlatinal

rheumatism, a bad name which quite gratuitously assumes a connection between this arthritis and rheumatic fever, for the existence of which there is no evidence.

Arthritis occurs commonly in association with *meningococcic meningitis* and *Malta fever*, less commonly with *dysentery*, rarely in association with *influenza*, *glanders*, *small-pox*, *measles*, and *diphtheria*. In all these cases the presence of the principal disease determines the diagnosis.

Gonorrhœal Arthritis is often called gonorrhœal rheumatism, but this phrase should be discarded, for there is no association between gonorrhœa and rheumatic fever. Gonorrhœal arthritis is frequently overlooked. I have repeatedly demonstrated its presence when the family physician has believed its existence impossible. It is particularly likely to be missed in women. I have met with it in married women of fifty: it is probable in these cases that they are infected by their husbands. It may follow gonorrhœal ophthalmia and even ophthalmia neonatorum. The diagnosis may be very easy, as when a patient is seized with an acute arthritis, either of a single joint or of several joints, while he or she is suffering from gonorrhœa. If it is possible to withdraw a little fluid from the cavity of the swollen joint the discovery of the gonococcus makes the diagnosis certain, but this is usually quite unnecessary, and unless done very carefully may, by introducing micro-organisms from without, greatly increase the damage to the joint. Often a urethra discharge may be found, though sometimes in long-standing cases of gleet it is very slight: if the gonococcus cannot be found in the discharge, it may be detected in a swab taken from the posterior urethra or vagina.

It is difficult from the clinical character of gonorrhœal arthritis to tell it certainly from other forms of arthritis. Mistakes happen least often to those who constantly think of the possibility. It is of varying degrees of acuteness: in the chronic cases of gleet the corresponding arthritis is chronic, but in the acute cases of gonorrhœa it may be so acute that it is often mistaken for rheumatic fever. Gonorrhœal arthritis may be limited to one joint, and then most often to a large one, especially the knee: but it may be multiple, and very many joints, even those of the wrists, hands, and fingers, may be implicated: there is often much swelling of the soft tissues around, and this is more responsible for the swelling than is the effusion in the joint. Gonorrhœal arthritis is usually very painful. The sheaths of tendons are often inflamed and tender, and so are some fasciæ, especially the plantar fascia. The patient often complains of pain at the back of the sole of the foot, and in a chronic case he has flat-foot. There is no variety of arthritis in which muscular atrophy is more striking. I have known a severe case of gonorrhœal arthritis of the hand called progressive muscular atrophy. When gonorrhœal arthritis is chronic throughout the whole of its course, and is limited to one joint, the cause of the trouble is often erroneously set down to tubercle. Suppuration is very rare. Some cases are extremely chronic, and may lead to fibrous ankylosis with deformities, but with our modern means of diagnosis and treatment this has become exceptional. Salicylates have no decided effect either upon the joint pains or upon the co-existent pyrexia (*Fig. 329*).

All the acute affections hitherto mentioned, except rheumatic fever, are often included under the phrase '*infective arthritis*', because they are known to be due to infection by a micro-organism: but this is a loose term that ought only to be used in a general sense, for a diagnosis of the precise cause of the infection is nearly always possible if care be taken. Sometimes in an infective arthritis there is more than one micro-organism at work to cause it: thus, in the late stages of gleet various micro-organisms flourish in the diseased urethra, and the arthritis may be due to a mixed infection in which the gonococcus is not the preponderating micro-organism. In exhausting diseases, e.g., typhoid fever, the patient may suffer from a secondary streptococcal infection which may cause arthritis.

Acute Secondary Arthritis. By this is meant arthritis due to spread of disease from the bone in the neighbourhood of the joint. It is limited to one joint: the most acute and dangerous form is that which follows acute osteomyelitis. More than once I have known this called rheumatic fever, because the onset has been sudden and the temperature raised. It is a most unfortunate mistake, for patients suffering from this form of arthritis are liable to die quickly from general septicæmia, to prevent which the joint ought to be opened and drained at once. The mistake may usually be avoided by remembering that rheumatic fever does not affect one joint only. The more difficult cases are those in which more than one joint is acutely diseased as a result of disease of the ends of the bones. To

avoid this mistake, disease of the bones themselves must be carefully sought. Fortunately for diagnosis, this disease of several joints is most frequent in infants, and in them severe arthritis due to rheumatic fever is unknown. It is called *acute arthritis of infants*. Disease of joints may be secondary to an abscess in the bone or to tuberculous disease of the bone. These varieties are diagnosed by discovering the underlying disease of the bones: X rays are often of much use.

Fig. 331. Chart showing the pyrexia of rheumatoid arthritis; the temperature was uninfluenced by salicylates.

fever; hence the name implies an arthritis resembling that of rheumatic fever. It would probably lead to worse confusion to invent a new name, so the present had better stand until the micro-organism causing the disease has been discovered. The first attack is ushered in with fever; the temperature is rarely higher than 100° or 101° F. in the evening and 99° or 100° F. in the morning. This fever lasts from three to six weeks, slowly subsiding towards the end (Fig. 331). The pulse is generally rapid, out of proportion to the fever, the hands and feet sweat freely, patches of freckle-like pigment are prone to appear on the body. Mostly the patients are young women. The pyrexia is less severe and longer lasting than that of rheumatic fever; the pulse is, considering the temperature, faster; the sweating is almost confined to hands and feet, pigment is frequent. Nor are the differences with regard

Fig. 332. Acute rheumatoid arthritis, showing the spindle-shaped swelling of the joints between the first and second phalanges, and the swelling in connection with the wrist and metacarpophalangeal joints.

Fig. 333. Pronounced spindle-shaped enlargement of some of the first interphalangeal joints, the result not of rheumatoid arthritis but of gout.

to the arthritis less striking, for in rheumatoid arthritis the characteristic joints to be affected are those between the first and second phalanges, and as it is an affection of the synovial membranes, and also considerably of the soft tissues around the joints, quite early in the disease we get a spindle-shaped swelling of these joints (Figs. 332, 333); but soon many other joints are affected, and before long almost every joint in the body, even the temporo-maxillary joint, is often involved; so is the spine. It will be noticed that in every respect the arthritis is clinically different from that of rheumatic fever. The joints never suppurate, but the epitrochlear gland may be found enlarged. Slowly the attack subsides; as it does so, passive

movements and massage should be undertaken, for if not, the thickening of the tissues around the joints leads to their fixation. That this may be prevented is shown by the fact that the jaw rarely becomes fixed, presumably because of its frequent movement. There is never any endocarditis. The arthritic muscular atrophy is often as extreme as

Fig. 334.—Severe rheumatoid arthritis: skeleton of the hands showing almost complete bony destruction and great changes.

Fig. 335.—Skeleton from a case of severe rheumatoid arthritis, with stiff, contracted fingers. The purpose of the illustration is to show that, though the fingers become much out of shape, the bones themselves do not depart from their normal outline; the disease affecting the soft parts and not the bones; the latter, however, show pitting of their ends, as the result of the restriction that is apt to occur in the bones in this disease.

in any variety of arthritis. In a few months a second attack comes on, but both the general symptoms and the arthritis are less severe than in the first; then a few months later another, less severe than the second, and so on, until after four, five, or six attacks the active phase of the disease wears itself out, though variable degrees of deformity, fixation and contracture remain. In the later stages, if the joints have been allowed to become stiff, the disease is often confused with osteo-arthritis; but rheumatoid arthritis occurs in younger subjects, and there are no bony outgrowths (*Figs. 334, 335*), except in a few cases in which chronically thickened fringes of synovial membrane have, by friction during movements of the joints, worn away a little patch of cartilage, exposed and irritated the bone, and led to a slight outgrowth. In such a case the erosion of the cartilage may lead to bony grating, but in even a very chronic and extreme case of rheumatoid arthritis, in which the joints have not been treated, bony outgrowths are quite inconsiderable, and are not a leading feature as in osteo-arthritis. Heberden's nodes (*Fig. 336*) are not seen in rheumatoid arthritis. The spindle-shaped swelling of the phalangeal joints of this disease is not seen in osteo-arthritis. The joints principally affected are different in the two diseases, as will be seen on reference to osteo-arthritis, and the history

Fig. 336.—Heberden's nodes on the terminal phalanges of the fingers; the figure also shows soft pads on the dorsal aspect of certain of the first interphalangeal joints.

is entirely different. Formerly some importance was attached to the transparency of the bones to the X rays in the neighbourhood of the affected joints which may be seen in rheumatoid arthritis (*Fig. 335*), but this is now known to be visible in other forms of arthritis.

Fig. 337.—Henoch's purpura.

The X rays are, however, of use in excluding the bony outgrowths of osteo-arthritis. In chronic cases of both rheumatoid arthritis and osteo-arthritis ulnar deflection may be seen (*Fig. 334*).

Henoch's Purpura.—This disease is confined to children between infancy and fifteen years old, and early in its course pain and slight swelling of some of the large joints, with a little elevation of temperature, are often present. As in children the pyrexia and arthritis of rheumatic fever are inconspicuous, mistakes have occurred between it and Henoch's purpura, but the pain in the latter is trivial. The attacks of abdominal pain, with perhaps vomiting and diarrhoea, are characteristic, and so is the purpura (*Fig. 337*), together, in many cases, with bleeding from some internal organ, hæmaturia, hæmatemesis, or melenæ. The purpura should not give rise to any difficulty: rheumatic purpura is unknown under the age of fifteen.

Gout.—This is often said to be present when it is not. The most certain points in the diagnosis of gout are, first, the detection of urate of sodium,

usually as white hard masses in connection with a joint (*Figs. 339, 341*), in a bursa (*Figs. 338–341*), or as a deposit in the cartilage of the edge of the ear (*Fig. 340*): here it is frequently not easy to be sure if a white nodule is urate of soda or a projection of cartilage with the skin stretched tightly over it. If it is possible to remove a minute fragment with a needle, crystals of urate of sodium may be seen under the microscope. Secondly, there may be a history of repeated characteristic attacks.

The gouty arthritis that we see nowadays is generally strongly inherited, but not often by women, and therefore the family history is of importance: it rarely shows itself before the age of twenty, though I have seen it in a boy fifteen years old. Most of the sufferers from gout now alive get their attacks

independently of any errors in

any of them are most abste-

The diagnosis is not difficult

if the patient has had one or more attacks of arthritis in the characteristic joint—that of the ball of the great toe, more often the right than the left: the attack usually begins at night with excruciating pain, which subsides towards early morning: the patient, exhausted with pain, drops asleep, to wake later and find his joint swollen and tense. There is some fever (*Fig. 330*, p. 424). Probably during the day his toe does not cause pain unless he walks on it: but he has another attack the next

night, not so severe as that on the first, and on each successive night the attacks are less. He may have another bout at any period of his life, and he may have many bouts, and other joints may become affected subsequently. The real difficulty in the acute cases

Fig. 338.—Skigram from a case of gout in the shoulder, showing uric acid deposits as a dim shadow in the subacromial bursa. The latter is indicated by the arrow. (*Fig. 10, B. H. Caldwell*.)

comes when it is suggested that an acute arthritis with pyrexia, and swelling and redness of a joint other than that of the great toe, is caused by gout: for instance when the joint affected is the shoulder (*Fig. 338*), the elbow, the wrist, or the knee. Such cases, if they are not gout, are some bacterial arthritis. If more than one joint is affected with acute arthritis at the same time, the probability is against gout, and the greater the number of joints affected the less likely is the case to be one of gout. The history and presence of urate of sodium are often conclusive in favour of gout. If pus forms, the case is almost certainly not gout, for gouty joints very rarely suppurate except late in the chronic disease. On the other hand, the implication of tendon sheaths and pain in the back of the soles of the feet are in favour of gout, though it must be remembered that both these occur in gonorrhoeal cases.

Fig. 338. Chronic gouty deposition of urate of sodium in and near the joints.

The presence of a source of infection is of course against gout. The difficulty is especially great in cases in which the general symptoms and arthritis, although gouty, are continuous rather than paroxysmal; but on the whole, continuously increasing severity of general symptoms is against gout. The goutily-inflamed joint looks especially shiny, is exquisitely tender on the surface, and is more painful at night than during the day. Cases of extreme difficulty have been recorded in which the first joint affected by pyæmia chanced to be that of the great toe.

Probably most examples of acute arthritis said to be gouty are so, but mistakes are common about *chronic gout*. Many patients with chronic arthritis are quite wrongly said to have gout: usually they have osteo-arthritis or rheumatoid arthritis. The presence of visible urate of sodium in places already mentioned

Fig. 340. Gouty tophi on the ear. The patient also had a small epithelioma of the floor of the mouth, infiltrating the neck and causing a sinus.

Fig. 341. Gout of the hand and of the olecranon bursa.

(*Fig. 339*), the history of previous acute attacks, the history of gout in ancestors, the age and sex, will all help. Tophi in the ears (*Fig. 340*) or urate deposits in the olecranon bursa (*Fig. 341*) afford direct evidence of gout. The presence of bony out-

growths is strongly against gout, though it is not conclusive, for such may occur in true gout, either more or less all round the joint, or in the form of little nodules: but they

never attain the considerable size common in osteo-arthritis. If no urate of soda is visible anywhere, the diagnosis may be very difficult: the reader should consult the principal points mentioned under the heading of osteo-arthritis. Any joints in the body

Fig. 342.—Chronic gout. Skiagram of the hands, showing sodium urate deposits about the end of many of the phalanges.

may be affected by gout, but it is very rare in the joints of the trunk, the shoulder, or the hip. The spine, shoulder, and hip are commonly affected in osteo-arthritis. Urate of sodium may be seen in and near the joints as light spots in X-ray prints (*Fig. 342*).

II. CHRONIC JOINT AFFECTIONS.

We will now pass on to consider the diagnosis of varieties of arthritis which are for the most part chronic, but it must be remembered that many of those mentioned as acute become chronic, and their diagnosis has been described.

Osteo arthritis is a chronic disease frequently confused with rheumatoid arthritis, though it is completely distinct, both clinically, and from the point of view of morbid anatomy. Rheumatoid arthritis is primarily a disease of the synovial membrane and the soft tissues of the joints. Osteo-arthritis is primarily a disease of the cartilage and bones, leading to the destruction of the cartilage, eburnation of bony surfaces, and the production of much new bone at the edges of the joint; hence bony outgrowths (osteophytes), grating of the joint, and locking of it so that movement is difficult, are common. Thickening of the synovial membrane occurs, but is less important: the ligaments become implicated and may soften: if so, the joint becomes flail-like; there may be some thickening of the tissues around the joint and some increase of synovial fluid, and then the joint becomes enlarged. It is easy to distinguish in most cases between osteo-arthritis and rheumatoid arthritis by the appearance of the affected joint, and by the fact that the former is often associated with a healthy facies whilst rheumatoid arthritis is a toxic condition with corresponding general appearance of ill health. Osteo-arthritis is often confined to one joint, and that a large one, e.g., the knee or the hip; rheumatoid arthritis affects many joints, and is most characteristically seen in small joints, e.g., those between the first and second phalanges; but when osteo-arthritis does show itself in small joints those most often affected are the terminal joints of the phalanges, where the bony excrescences form Heberden's nodes (*Fig. 336*, p. 427). Rheumatoid arthritis is far more common in young

women; osteo-arthritis in elderly men. Rheumatoid arthritis nearly always begins with fever, although often slight; osteo-arthritis is afebrile. The pulse is often rapid in those who have active rheumatoid arthritis; it is not particularly affected in those who have osteo-arthritis. The spine is more often affected by osteo-arthritis than rheumatoid arthritis, and it is quite common in the dissecting-room to find that elderly subjects have osteo-arthritis of the spine. Muscular atrophy is far greater with rheumatoid arthritis than with osteo-arthritis. Osteo-arthritis is especially liable to attack the hip—usually only one—and this form is commonest in elderly men, *morbus coxae senilis*. Great care must be taken to distinguish the pain due to this from that of sciatica. The chief point of distinction is that in the latter the nerve itself is tender to pressure; but it must not be forgotten that in very rare cases osteo-arthritic outgrowths from the hip may implicate the sciatic nerve and so cause genuine sciatica. Although osteo-arthritis of the hip usually causes lameness, so many other conditions do this, e.g., sacro-iliac disease, that the symptom is of little value. The knee is another joint often affected by osteo-arthritis—usually both, but sometimes only one is implicated. This disease of the knee is common in women of ages between forty-five and fifty-five. They complain of pain and stiffness. Often the pain and tenderness, if present, are confined to one spot. There is usually considerable enlargement of the joint, bony irregularities may be felt, and grating and crackling on movement are very common; these are due to bony outgrowths, erosion of cartilage, and thickening of synovial membrane, which also gives a feeling to the observer's hand placed over the joint when it is moved as though he were feeling the movement of wet sand in a bag. The grating may be heard loudly through the stethoscope. Other joints often implicated in osteo-arthritis are the shoulder, elbow, ankle, wrist, and temporo-maxillary joint; but what has been said about the disease in general, and that of the knee in particular, applies to them. The disease may be considerably advanced and yet confined to one joint, or any number may be affected. X-ray examination is of valuable assistance in arriving at the diagnosis; with rheumatoid arthritis there may be rarefaction of the bony trabeculae and thinning of the intra-articular cartilage, but the outlines of the bony ends are normal or nearly normal unless the disease has reached a very late stage; whereas with osteo-arthritis the deformity of the bone ends and the osteophytes at their margins are characteristic.

In connection with the knee, a condition which is sometimes mistaken for arthritis, because pain in the knee is the complaint, is a painful state of either the semimembranosus bursa or of the internal semilunar cartilage resulting from recurrent slight injury or from the pressure of one knee against the other during sleep; the diagnosis suggests itself when tenderness is confined to a local spot corresponding to either the bursa or the cartilage, and is confirmed when the pain disappears when a simple soft pad is worn on one knee at night, to prevent it being injured by the pressure of the other. The condition may be bilateral. The points which have been especially mentioned as helping to distinguish osteo-arthritis from rheumatoid arthritis will aid in the distinction of it

Fig. 343. Palpation of the dorsal aspect of hands, illustrating the difference between osteo-arthritis and rheumatoid arthritis. (By permission from 'The Quarterly Journal of Medicine', 1912, 12.)

Fig. 344. Skiagram showing the pads depicted in Fig. 343 affect the soft parts and not the underlying joints. (By permission from 'The Quarterly Journal of Medicine', 1912, 12.)

from other forms of arthritis. Pads (*Fig.* 336, p. 427, and *Figs.* 343, 344) on the dorsal aspect of the joints between the first and second phalanges are not rare. They vary in size from a split pea to a hazel-nut. The joints are not diseased, but these pads, which are due to overgrowth of fibrous tissue underneath the corium, have been confused with osteo-arthritis. They are often associated with Dupuytren's contracture (*Figs.* 152, 153, p. 179). Ulnar deflection (*Fig.* 334, p. 427) is seen in osteo-arthritis, but is also present in so many other affections of the fingers and wrist that by itself it is of no value in diagnosis.

Tuberculous Disease of Joints. This is most common in children of between three and five years, and becomes rarer as age advances. About 40 per cent of the cases are in the spine, 40 per cent in the hip, 10 per cent in the knee, and the other joints which are affected not uncommonly are the ankle, shoulder, elbow, and wrist. The disease is essentially slow, so that the early stages are often overlooked. It is stated that tuberculous arthritis is so insidious in its onset that for one case in which the affection is detected and adequately treated in the first month of its existence, there are twenty in which it is allowed to drift on for three or four months, or even longer, before it is recognized. For some time there may be only slight transient impairment of movement, or an occasional twinge of pain; gradually impaired movement, showing itself as slight lameness in the lower extremity, becomes evident, but it must not be concluded that there is no tuberculous disease of a joint because there is no impairment of movement. In the same way, although pain, often worse at night, and causing screaming, is an important sign, yet pain may be absent for a long while, or altogether. In all the joints except the shoulder and the hip which are so deeply covered by soft parts that unless it is considerable it cannot be detected—swelling is a very important symptom, for it is almost invariably present, even in the earliest stage. It may be very slight. Although there may be no defect of movement in the early stages, sooner or later, and often quite early, this symptom develops and is of great value. Tuberculous arthritis is usually accompanied by wasting of muscles moving the joint. It is rare for more than one, or perhaps two, joints to be affected in the same person; tuberculous disease elsewhere, e.g., phthisis, is not common; lardaceous disease, formerly so frequent a complication, is now seldom seen; and general symptoms, e.g., pyrexia, are often absent and rarely extreme; on the other hand, those affected are often pale. Bony outgrowths are not to be detected; the joint is swollen and feels thick; hence the phrase 'pulpy knee'. There is often a history of injury to a joint which later becomes tuberculous, and then the transition from a traumatic to a tuberculous arthritis is often overlooked. Tuberculous disease of the sacro-iliac joint is particularly difficult to diagnose. Tuberculosis of the hip is often overlooked because the pain is referred to the knee, and the slight wasting of the hip muscles is not detected.

Acquired Syphilitic Arthritis. This is most easily recognized by those who constantly bear in mind the possibility of its existence. If the characteristic pains of syphilis, which are usually worse at night, happen to occur near a joint, they may be ascribed carelessly to gout or osteo-arthritis. In the secondary stage of syphilis, and more particularly early in it, syphilitic synovitis of any joint may occur. It is subacute, slow, is attended with moderate swelling, and occasionally tenderness, and usually is confined to one joint. Pain may be present, but commonly neither pain nor tenderness is a prominent symptom. There is some, but not much, enlargement of the joint from distention with synovial fluid; in a few cases the size of the joint varies considerably in a short time. These cases are often mistaken for tuberculous arthritis, but the error can usually be avoided if the patient is examined carefully and questioned for other evidence of syphilis; and in this, and all other forms of arthritis in which there is any possibility of syphilis, a Wassermann test should be done. Syphilitic arthritis in the tertiary stage is rare; there are two varieties of it, both of which produce considerable swelling and disorganization of the joint; in one there is a deposit of gummatous material in the subsynovial tissue, in the other in the ends of the bone. Both varieties are usually confined to a single joint, neither is painful, and both are liable to recur. Great effusion of synovial fluid is not common, but when the disease is in the subsynovial tissues the joint is enlarged and the thickening of the synovial membrane can be felt.

Congenital Syphilitic Arthritis. In children and young adults congenital syphilis may cause an arthritis which is very like that caused by tubercle. The knees are affected most

often, and the disease is often symmetrical. If there is much synovial exudation fluctuation is detected easily: if there is much gummatous deposit in the subsynovial tissue the synovial membrane feels thickened and irregular. There is no pain, and very little impairment of movement. The existence of this disease must always be remembered; the history and examination for other signs of syphilis, especially nerve deafness or interstitial keratitis, must be thorough, and the Wassermann reaction must be tested.

In *infants* congenital syphilis may cause osteochondritis in the sub-epiphyseal plate of cartilage and adjacent bone: the epiphysis becomes separated from the shaft, so that there is motility and dull grating, as if a fracture had occurred. At the same time there is considerable swelling of the soft parts around, from the inflammation having spread to them, so that there is much swelling about the joint although the joint itself is usually not implicated. Separation of the epiphysis from the shaft makes the limb paralysed: hence the phrase *syphilitic pseudo-paralysis* applies to this condition. Suppuration is rare, improvement with mercury is rapid. This condition may be noticed at any period from one month after birth till the age of two or three years, but it is most often seen when the child is two or three months old. It may be multiple. There is some tenderness and slight pain. Other signs of congenital syphilis are generally present: but if not, and the condition is suggestive, the child should be given mercury and the effect watched.

Intermittent Hydrarthrosis. This rare disease should be diagnosed easily. It is commonest in women. Cases have been recorded between the ages of eight and fifty, but the patients are most often between twenty and thirty years old. Fluid is poured out rapidly in the joint, so that it becomes much swollen in a few hours: the distention attains its maximum in one or two days: it then recedes, and has disappeared by the fourth or fifth day: after an interval of perhaps a month the phenomena recur in the same joint: and thereafter at almost regular intervals. It is the periodicity of the effusion that gives the diagnosis. The effusion leads to stiffness of the joint, and generally there is some pain, but usually very little tenderness, and the joint is neither red nor hot. The knee is affected most often: it may be one or both knees: if not the knee it is almost always a large joint that is the seat of the effusion. It is rare for more than two joints to be affected at once. It may be that for a period the intervals are of a certain length, and then for a period they are of a different but uniform length. In other cases there is no regular periodicity. After three or four years the attacks cease in most cases, but occasionally there are recurrences over still longer periods.

Charcot's Disease (Fig. 345). This is the arthritis met with in tabes dorsalis, and if any patient, of such an age that he could be suffering from tabes, has chronic arthritis of a single joint, we ought always to examine him for signs of tabes: the arthritis may exist even when the patient is unaware that he has any signs of tabes. There is nothing characteristic of tabetic arthritis unless perhaps its relative painlessness, and many joints

Fig. 345. Charcot's disease of the right knee joint in association with tabes dorsalis. Shows distortion of the joint and loss of movement of the tibia to the extent of right.

Fig. 346. Skiagram of Charcot's disease of the hip joint. The appearances are typical and diagnostic: they show extensive destruction of the normal bone and large masses of abnormal new bone thrown out around it. The diffuseness and lack of definition of the bony outlines are characteristic. (By Dr. C. Theissen, Holland.)

affected with it might, for all the clinical symptoms of the arthritis, or from the appearances after death, be equally well affected by osteo-arthritis: but the following points will often make one suspicious. The effusion is frequently very great—some of the biggest joints seen are those affected by tabetic arthritis: the ligaments may be much softened, so that the joint becomes flail-like, but the growth of new bone at the edges of the joint is often quite

Fig. 347.—Antero-posterior skiagraph of an elbow-joint, showing the destructive changes that may accompany Charcot's disease; from a case of tabes dorsalis.

Fig. 348.—The same joint as that of *Fig. 347*, but seen in the lateral view, showing the destructive changes.

Compare *Figs. 349, 350*, for similar changes that may develop in the hip-joint.

Fig. 349.—Antero-posterior skiagraph showing the destructive changes that may be undergone by the femoral head of the hip-joint in the course of Charcot's disease in a case of syringomyelia.

Fig. 350.—The same joint as that of *Fig. 349*, but seen in the lateral view.

(*Obs. Dr. J. H. Mather.*)

slight, and there is considerable atrophy of bone: thus I have seen the floor of the acetabulum as thin as paper, and because it was so thin, the pressure from the neck of the femur had expanded the floor of the acetabulum so far into the pelvis that it formed a large projection into the pelvic cavity. Tabetic arthritis is usually chronic and never acute, but it may be rapid: thus there may be advanced destruction of the joints in a few weeks (*Figs. 346-348*); it is almost always painless; generally large joints—e.g., knee, hip—are affected; usually only one joint, but I have seen two. The rarefaction of the bones

makes them liable to fracture. When tabetic arthritis occurs in the bones of the hand or foot the considerable swelling may cause it to be mistaken for tuberculous disease. In 75 per cent of cases of tabetic arthritis the joints affected are those of the lower extremity.

Arthritis in Syringomyelia. In 75 per cent of the patients affected with this form of arthritis the joints affected are those of the upper extremity. There is nothing absolutely distinctive of this variety; it resembles closely the Charcot's joint of tabes (*Figs. 349, 350*); perhaps, on the whole, some of the cases more nearly resemble osteo-arthritis. Mistakes in diagnosis can only be avoided by always having in mind the possibility of the occurrence of syringomyelia, and examining the patient for it, especially the loss of sensation to heat, cold, and pain with preservation of ordinary cutaneous sensibility. Happily it is rare, and often the symptoms of syringomyelia (p. 752) are evident before the arthritis shows itself. In about half the cases of syringomyelia there is scoliosis of the spine.

Arthritis in Hæmophilia. In this disease blood may be poured out into either the synovial membrane or the cavity of the joint. This is probably always the result of a blow, often so slight as to pass unnoticed. It is most common in the knee and ankle. If the bleeding is at all considerable the joint swells, the rate of swelling depending upon the rate of effusion of blood. The joint is puffy; there may be fluctuation, pain on movement, and tenderness. The whole trouble often subsides, but sometimes more or less swelling persists for a time, and even if a joint gets well, relapse is likely. In other cases, either the impaired blood-supply resulting from damaged vessels or the friction of the clots leads to erosion of the cartilage, and permanent disease of the joint results. Forgetfulness of the fact that disease of the joints occurs in hæmophilia has led to the serious mistake of incising one into which bleeding has occurred. The condition is to be diagnosed by observing the other signs of hæmophilia.

Malignant and Hydatid Disease of Joints. Both these are very rare, and in each case the disease almost always begins in the adjacent bone, and therefore properly belongs to diseases of bones. Both are very serious; hydatid disease of a joint is very liable to lead to suppuration in it.

Displacement of a Semilunar Cartilage may cause much synovitis, and the cause of the latter is very apt to be overlooked. There is often a history of a wrench, or the patient complains that he feels something in the joint slip or catch; this may cause considerable pain, and there is often tenderness over the internal semilunar cartilage. Sometimes similar symptoms are produced by a thickened fringe of synovial membrane becoming nipped. This may occur in osteo-arthritis. The thickened fringe may become detached, and then it forms a loose body inside the joint.

Nervous Mimicry, Neuromimesis, or Hysterical Joints. In these cases some of the symptoms of arthritis are imitated without there being any actual disease of the joint. It is important to remember that hysteria is a disease and is not mere malingering. The malingerer can voluntarily get rid of his supposed disease if he wishes; the hysterical girl cannot, as she has not sufficient power of will. There are three main varieties: (1) The joint is kept constantly in an abnormal position, e.g., the knee may be considerably flexed; (2) The joint cannot be moved, e.g., the hand may hang down from the wrist, as in extensor paralysis, and it cannot be raised; (3) There may be acute pain in the joint. In all these cases careful examination will usually show that there are no real symptoms of arthritis: there is no swelling, no heat, no grating, no bony outgrowth, the immovably fixed joint can be moved freely under an anæsthetic; on the other hand the pain, if present, is far in excess of any pain due to arthritis, and the tenderness may be so great that the patient will not let the joint be touched. Both pain and tenderness disappear if the patient's attention is diverted, and neither keep him awake nor affect the general health. The pain may radiate far beyond the joint. Very rarely in hysteria there is trivial swelling, but it is not such as would be produced by the distention of the synovial cavity; it is often more in the neighbourhood of the joint than over it; but nearly always there is no swelling about a hysterical joint. Usually the joint supposed to be diseased is cold; very rarely it is hot and perhaps a little red; but this phenomenon, when present, is only a local blush due to the fact that the patient's attention is directed to the joint, and it passes away quickly. The stiffness of a hysterical joint can be made out to be due to contraction of muscles and not to alteration of the joint itself; occasionally it is variable, and often extreme, out of all proportion to any possible joint disease; often, too, the attitude of

the joint is not that usually seen in arthritis. Muscles which move a joint usually atrophy, often rapidly, when that joint is diseased, quite apart from disease : in hysterical affections

of joints the muscles waste only slowly in proportion to the disuse of the joint.

Muscular Paralysis. Often, e.g., in peripheral neuritis, the muscles which undergo rapid wasting as a result of disease of the lower motor neuron soon begin to contract, and this leads to considerable alteration in the usual position of joints. Thus the knee and the elbow become strongly flexed, and at first it may be thought that these unusual positions are the result of disease of the joint, for long-continued chronic disease of a joint will lead to unusual permanent positions from contracture of ligaments, from the pull of muscles on a weakened joint,

Fig. 351.—Pulmonary osteoarthropathy; the patient had chronic thrombophlebitis. The bony parts of the fingers were becoming progressively thicker, especially in the right hand.

and from contracture of muscles wasted from arthritic atrophy : but a little estimation of the history, the condition of the joints, the symptoms of nerve disease, and the electrical reactions of the muscles will soon lead to a correct diagnosis. There is no reaction of degeneration in muscles that have atrophied secondarily to arthritis.

Hypertrophic Pulmonary Osteoarthropathy is rare and not really a disease of joints at all, for the change consists in an enlargement of the ends of the bones, and hence the joints appear large and the patient cannot bend them properly. Often this is all that is the matter with them, but in advanced cases there is some thickening of the synovial membrane and some erosion of cartilage. The upper extremity is affected more often than the lower, and the joints usually deformed are the wrist, and the carpal and interphalangeal joints (*Figs. 351 and 352*) : when the condition exists in the lower extremity the corresponding joints are implicated. In extreme cases the enlargement extends up the shafts of the affected bones. The condition is distinguished easily, for it is almost always accompanied by clubbing of the fingers, and in 80 per cent of the cases it is associated with chronic pulmonary disease, especially fibrosis, bronchiectasis, phthisis, or chronic empyema, of which there are generally ample physical signs. The remaining 20 per cent of the cases are associated with such diverse conditions that text-books must be consulted ; the most interesting is aneurysm of the subclavian artery. Hypertrophic osteoarthropathy used to be confused with acromegaly : not only ought the clubbing of the fingers and the associated conditions to prevent such a mistake, but in acromegaly there is also considerable enlargement of the head, characteristic changes in the face (see *Fig. 250*, p. 293), and an increase in the size of the pituitary fossa as seen in a lateral skiagram of the skull (*Fig. 310*, p. 379),

Fig. 352.—Pulmonary osteoarthropathy of the hands and feet in a case of chronic phthisis.

KELOID. (See CHELOID, p. 131.)

KIDNEY, ENLARGEMENT OF.—A renal swelling may be so slight that it is only found upon clinical examination, or it may be large enough to attract the patient's attention. A number of pathological changes in the kidney may give rise to a tumour of that organ, such as hydronephrosis, pyonephrosis, renal tuberculosis or abscess, new growths, and various forms of cysts in the kidney: they have to be diagnosed not only from one another, but also from other tumours simulating a renal swelling.

The chief characteristic points of a renal tumour are:

1. *The large intestine is in front of the tumour.* When either kidney is merely slightly enlarged, both large and small intestine will be in front of it; but when the organ is so enlarged as to reach the anterior abdominal wall the coils of small intestine are pushed aside. The anatomical relation of the large intestine to the kidney, and the absence of a mesentery, do not allow of the same mobility of the colon, which retains its position in front of the kidney. Hence an area of resonance can usually be obtained in front of a renal swelling: if the colon be empty it can sometimes be felt in a thin subject and rolled by the fingers on the surface of the tumour. Bowel is never placed in front of a splenic tumour, and only rarely in front of a hepatic tumour.

2. *The area of dullness to percussion* is continuous from the lateral aspect of the swelling to the mid-line posteriorly—that is, there is no area of resonance between the mass and the vertebral spines, as in a splenic or ovarian tumour.

3. A renal tumour usually *retains the shape of the kidney*: it is rounded at its borders and poles, and does not possess any edge or sharp margin, as in splenic or hepatic swellings.

4. A renal tumour in the process of enlargement *projects forwards and downwards*. It may fill up the natural hollow of the loin, but very seldom causes any prominence posteriorly. A perinephric abscess, which often simulates a renal swelling, may cause a distinct prominence in the loin.

5. A renal tumour may be movable downwards or inwards, unless it is fixed in the loin by preceding inflammation: an enlarged kidney can be felt bimanually, and if grasped between the two hands *can be pushed into the loin*. A renal tumour rarely descends into the iliac fossa.

6. When a renal tumour is large enough to reach the anterior abdominal wall it commonly comes in contact with the latter at the level of the umbilicus, at the same time bulging out the ilio-costal space. There is usually a line of resonance between the upper margin of the tumour and the hepatic dullness.

7. A *varicocele* may be developed on the same side as the renal tumour. This is especially significant on the right side.

8. With a renal tumour there may be *changes in the urine* pointing to renal disease; but on the other hand, the urine at any one time may be normal, free from blood or pus, from the fact that the ureter of the diseased side is blocked, or that the disease does not involve the renal pelvis.

9. In exceptional cases, a tumour of the right kidney may extend upwards into the dome of the diaphragm, rotating the liver so that the anterior margin descends below the costal margin, and prevents satisfactory palpation in the renal area.

Although, from the above physical characters, it would seem that a renal tumour should present little difficulty in diagnosis, yet it is by no means infrequent to find that a tumour possessing several of these characters may give rise to considerable doubt in the determination of the organ from which it arises. The following points will assist in the diagnosis of renal swellings from other tumours with which they are likely to be confused:—

1. **Tumours of the Gall-bladder** (p. 314) are placed immediately below the costal margin, so that no interval exists between the tumour and the lower margin of the liver. They are usually oval in outline, with the long axis in the line between the ninth costal cartilage of the right side and the umbilicus: are freely movable with the respiratory movements, and movable from side to side about an axis at the costal margin. There is dullness on percussion over them, and they cannot be felt in the loin or be grasped bimanually. With a tumour of the gall-bladder there may be attacks of colic, with or without jaundice. A good skiagram may show the outline of a distended gall-bladder distinct from the shadow of the kidney.

2. Enlargements of the Liver (p. 461) pass downwards from beneath the costal margin so that there is no line of resonance, or area in which the hand can be depressed, between the tumour and the costal margin. Hepatic tumours do not impair the normal resonance in the loin in the same manner as a renal tumour does. A tongue-shaped lobe of the liver (Riedel's lobe) may cause difficulty in diagnosis: but here the lower margin is seldom so rounded as is that of a renal tumour, nor will the mass be felt in the loin on bimanual examination. A tumour or cyst in the concave aspect, or of the left lobe, of the liver is especially liable to cause error in diagnosis, whereas, on the other hand, a tumour of the right kidney which projects upwards behind the liver may so rotate the latter that its anterior margin descends below the costal margin and completely obscures the kidney. In a case of a large carcinoma of the right kidney, the liver may in this way be so depressed as to render palpation of the kidney impossible.

3. Enlargements of the Spleen (p. 774) descend from beneath the left costal margin, and have no bowel in front of them. The edge of a splenic tumour is usually well-defined and often notched, and there is resonance between the posterior aspect of the tumour and the spinal column. A splenic tumour is more movable than is a left renal tumour. A blood-count may help in deciding in favour of a splenic enlargement.

4. Perinephric Effusions, whether of blood, pus, or urine, may form a tumour in the loin which upon physical examination may be mistaken for a renal swelling. A perinephritic effusion may arise from some suppurative condition of the kidney, so that the previous history and examination of the urine will not assist in differentiation: or it may be due to conditions entirely distinct from renal disease. An effusion of blood around the kidney is, in nearly all cases, caused by an injury to the loin, and will be accompanied by other signs of injury. A perinephric abscess forms a less well-defined tumour than that caused by a renal swelling, is more acute in its general symptoms, such as pain and temperature, and fills up the ilio-costal space. The skin over it may be thickened or oedematous, and fluctuation may be felt to be more superficial than in a renal swelling. A perinephric abscess may result from suppuration about a carcinoma or diverticulum of the large bowel, from appendical inflammation, or from suppuration in a perinephric hæmatoma due to injury: it may be a sequel to a specific blow, or be due to a hæmatogenous infection. Bilateral palpation and comparison of the loins may detect perinephric swelling by the way the loin gets filled out and even convex on the affected side.

5. Tumours arising from the Pelvic Organs, from the ovary or uterus, may in some cases simulate renal tumours. An ovarian cyst with a long pedicle occupying the loin may be mistaken for an enlarged or movable kidney, and any sudden attacks of pain occurring from torsion of the pedicle may be looked upon as due to renal colic. The usual ovarian cyst or uterine fibroid will seldom be confused with a renal swelling, for it is placed in the middle line of the body, can be felt to come up from the pelvis, and can be felt readily upon bimanual vaginal examination to be attached to the uterus or its appendages. These tumours also give rise to dullness anteriorly, and do not alter the normal resonance in the loin. In cases of malignant ovarian tumours associated with ascites the lumbar resonance may be lost, but on turning the patient over on one side the previously dull note becomes replaced by resonance in the uppermost loin. In the case of an ovarian cyst with a long pedicle, or of a uterine fibroid of pedunculated, pediform form, the position in the loin may sometimes suggest a renal tumour: it will, however, be found to occupy a more anterior position in the abdomen than a renal tumour, and to possess a much greater range of movement, and it does not slip back into the loin under the costal margin in the same manner as an enlarged kidney does: there is resonance posteriorly, the kidney may be actually palpated as well as the abdominal tumour, whilst a distinct connection with the pelvic organs can sometimes be traced from the tumour when the latter is drawn up.

In contradistinction to the above a very large cystic renal swelling may be mistaken for an ovarian cyst. It may occupy the greater part of the abdomen, and even be felt per vaginam to be encroaching upon the pelvis: but on careful examination in a renal tumour of this form there will be no line of resonance between the mass and the vertebral column posteriorly, the natural hollow of the loin will be filled up, and there is frequently a distinct bulging in the lower thoracic wall, together with an increased length of the ilio-costal space on the affected side. Some assistance may be obtained from the history,

when a hydronephrosis may have been first noticed as a tumour commencing under the costal margin, and gradually increasing downwards towards the iliac fossa and inwards across the median line, whereas an ovarian tumour may have been noticed to increase upwards from the pelvis.

6. Suprarenal Tumours may occasionally be of sufficient size to form an abdominal tumour, presenting a rounded, movable swelling in the hypochondrium. It is often impossible to distinguish them from renal tumours without laparotomy.

7. Faecal Accumulations in the Colon, Cæcum, or Sigmoid flexure may give rise to a tumour and pain of a colicky nature in the loin. They will be distinguished from renal swellings by the general intestinal symptoms, flatulence, and the changes in form consequent on the administration of large enemata. It must be remembered that a patient with a collection of faeces in the colon may not complain of constipation, but may in fact have a small daily evacuation from the overloaded bowel.

8. Inflammatory Thickenings about the Appendix will be diagnosed from renal tumours by the situation of the pain and by the swelling being in the iliac fossa rather than in the loin. In some cases, however, the pain may be referred to the lumbar region, or an appendical inflammatory thickening may spread upwards. The onset of the trouble, the acute symptoms, and the febrile disturbance will usually distinguish these cases from renal lesions.

9. Malignant Growths of the Large Intestine, especially of the ascending or descending colon, may form a tumour in the loin which closely resembles a renal swelling. The mass formed by the growth may be grasped bimanually, is movable in the same directions as a renal tumour, and comes forward under the costal margin. The percussion note over the front of the lump is resonant, and there is usually an aching pain in the loin. If the growth has infiltrated through the wall of the bowel uncovered by peritoneum, the perirenal tissues may be thickened, or albuminuria may be produced by direct invasion of the kidney, when the case will even more resemble a renal lesion. Cancer of the large intestine should be suspected if there is any irregularity in the action of the bowels, mucus or blood in the motions, or any symptom of commencing obstruction in the intestine. The tumour may be irregular and nodular, whereas a renal tumour presents rounded margins. The occurrence of a tumour in either side, associated with discomfort or palpable distention of the cæcum from the accumulation of faeces, would render a growth in the colon the more suspicious. The appearances seen with the X rays at a suitable interval after a barium or bismuth meal or after a barium enema (*Fig. 140*, p. 161, and *Figs. 142-144*, pp. 163, 164) may assist the diagnosis by showing organic intestinal stenosis. Pycelography will show a shadow of a normal renal pelvis (*Fig. 353*).

10. Tumours of the Omentum, Mesentery, or Pancreas, either cystic or malignant, are more median in position, do not project into the loin, and seldom resemble a renal tumour.

In many cases in which difficulty arises in the diagnosis of a swelling in the loin, great help may be obtained by pycelography—that is, the injection into the renal pelvis by means of a ureteric catheter of some radio-opaque substance such as collargol in a 7 per cent solution, or sodium bromide 20 or 25 per cent solution, followed immediately by radiography. By this means the renal pelvis may be definitely outlined in its normal

Fig. 353. Skigram of a perfectly normal kidney, the upper border of which is indicated by the arrow. To the upper side of the kidney shadow is seen the oblique fibres of the psoas muscle. (*After W. H. Osbald.*)

position, and any change in position or shape may indicate that the swelling is of renal origin.

THE DIFFERENTIAL DIAGNOSIS OF RADIOGRAPHIC SHADOWS IN THE ABDOMEN AND THE PELVIS.

It is necessary for the true interpretation of radiographs that a clear conception should be held of the various conditions which may cast a shadow on an X-ray negative. In the diagnosis of cases of urinary disease much information may be gained by the use of X rays, and not merely in the confirmation of the presence of calculi in some part of the urinary tract: in a good negative the outline and the size of the kidney can be seen (*Fig. 353*), whilst, by means of the injection of the ureter and the pelvis of the kidney with a radio-opaque solution, the size, position, and shape of either may be outlined accurately and compared with the normal. Whereas formerly only the presence of a distinct shadow was of value, the recent advances in radiology render a negative report, except in the few instances of a calculus of pure uric acid, almost of equal value.

Fig. 354. Skiagram of multiple branched renal calculus.
(*Bo Dr. Knorr.*)

Fig. 355. Skiagram taken in the transverse axis of the patient, showing the position of the shadow of the stone (as *Fig. 354*). Note the position of the shadow in relation to the lumbar vertebrae; an ability to be increased upon the latter. (*Bo Dr. Kn.*)

In a good negative after efficient alimentary treatment the outline of a normal kidney should be visible, lying opposite the bodies of the first, second, and third lumbar vertebrae (*Fig. 353*), and having an excursion of from $1\frac{1}{2}$ to 2 inches in forced inspiration and expiration.

A renal calculus in a radiogram will cast a shadow superimposed upon the renal shadow.

If it is of triangular or branched outline (*Fig. 354*), it is almost certainly a renal calculus; but others may give a shadow of even, uniform density, of sharp outline, yet clearly distinct from the renal shadow, as shown by the way the opacity moves equally with the renal shadow in inspiratory movements. In a negative taken laterally through the transverse axis of the patient, a renal calculus should make a shadow superimposed upon the bodies of the upper lumbar vertebrae, usually the second (*Fig. 355*), unless the kidney is enlarged, when the shadow of a calculus may be displaced in front of the vertebral bodies. It should always be remembered that a stone composed of pure uric acid may give no shadow on a radiogram: one of calcium oxalate gives the most dense shadow; next in order of density is the phosphatic; those of urates, cystin, and xanthin give a less definite shadow; those of uric acid one less definite still.

There are, however, several other conditions which may cast a shadow in the renal area, and it is necessary to differentiate these from the shadow of a renal calculus. The following are the most frequent:—

1. Intestinal contents
2. Calcification of mesenteric glands
3. Gall-stones on the right side
4. Calcification of the costal cartilages
5. Caseous masses in a tuberculous kidney
6. Phlebolith.

1. *Intestinal Contents* may cast a shadow in the renal area owing to inefficient preparation of the patient or to the fact that he has recently taken as medicine bismuth, magnesium salts, etc. If any doubt exists a second examination should be made after further purgation.

2. *Calcification of the Abdominal or Mesenteric Glands* may cause a shadow in any part of the abdominal cavity. Though they are most frequently seen near the lower

Fig. 354. Skia-gram showing the lateral shadow of a highly calcified gland of the pancreas. It is situated in the renal area, just below the upper left border of the kidney, and is two inches or more from the position of the renal pelvis, but is also in the shadow of the kidney. The gland is about four inches in diameter. (Chas. Dr. Knorr.)

Fig. 357. Skia-gram of a vesical gall-stone. Note the position of the shadow of the peritoneum. (Chas. Dr. Knorr.)

lumbar vertebrae or about the sacro-iliac joint, and therefore external to the renal shadow, they may be superimposed upon the latter and cause difficulty in diagnosis. The shadow of a calcified gland is usually mottled in appearance, small areas in the shadow showing increased density owing to the irregular deposition of lime salts; calcareous glands are frequently multiple, but the chief characteristic of them is their range of mobility. Thus

Fig. 358. Skia-gram showing shadows of multiple gall-stones in the gall-bladder. (Chas. Dr. Knorr.)

Fig. 359. Skia-gram showing shadows of multiple small gall-stones in the fundus of the gall-bladder, and of one impacted in the cystic duct. (Chas. Dr. Knorr.)

if more than one negative is taken with varying degrees of compression the shadows of calcareous glands may show a varying position with regard to the renal shadow, whilst in a lateral view a glandular shadow is usually in front of the bodies of the vertebrae and not superposed upon them as in Fig. 355. A calcified gland may be placed immediately in front of the kidney and move equally with it, causing great difficulty in diagnosis; or

there may be calculus in one kidney and calcareous glands imitating calculi in the other, as in *Fig. 356*, which shows a large branched calculus in the right kidney, and on the left side two smaller shadows in the situation of the renal pelvis which appeared to be calculi; on repetition of the examination these shadows on the left side were placed at a much lower level and were then seen to be entirely extra-renal.

3. *Gall-stones* may give a shadow in the renal area on the right side. They are frequently multiple, and may be seen to be faceted in a fusiform collection presenting the shape of the distended gall-bladder. A single gall-stone superimposed on the renal shadow may cause difficulty; the shadow of a gall-stone is less dense than is that of a renal stone, and it is frequently less dense in the central than in the peripheral part (*Figs. 357-359*). In a lateral view a gall-stone in the gall-bladder will occupy an anterior position in the abdomen, though one impacted in the common bile-duct may be seen opposite the body of the first or second lumbar vertebra.

4. *Calcification of the Costal Cartilages* may give a shadow in the renal area in an antero-posterior negative. The shadows are not dense, are hazy in outline, and tend to assume a horizontal or oblique axis. In a lateral view they will be placed immediately under the anterior abdominal wall.

Fig. 360. Skiagraph of a renal calculus in the right kidney.

Fig. 361. Skiagraph of a renal calculus in the left kidney.

5. *Caseous Mass in a Tuberculous Kidney.* The shadow in this condition is rarely so defined as is that of a calculus, is of moderate density with blurred and indistinct margins, appearing as one or more blotches in the renal area; but occasionally, from the presence of lime salts, it may be very like the skiagraph of a calculus (*Fig. 287*, p. 352).

The line of the *normal ureter* lies anatomically along or just internal to the tips of the transverse processes of the second to the fifth lumbar vertebrae, passes with a slight curve outwards in front of the sacro-iliac articulation, and then with a marked curve forwards and inwards to the base of the bladder. A shadow in this line may be due to a calculus in the ureter, but it must be differentiated carefully from other conditions. A calculus is usually small, rounded or oval, with a long axis in the line of the ureter (*Figs. 360, 361*). It may be found in any part of the course of the ureter, but is seen most frequently in the terminal end just before it enters the bladder (*Fig. 362*). The conditions which may give a shadow likely to be mistaken for a ureteric calculus are:

1. A calcified lymphatic gland.
2. A concretion in the appendix or the intestinal contents.
3. Phleboliths in the pelvis.

1. *Calcified Lymphatic Glands* in the line of the ureter are placed most frequently in the angle between the last lumbar vertebra and the ala of the sacrum. They are usually multiple, forming a group in this situation in triangular form (*Fig. 363*) rather than in the longitudinal axis of the ureter; they are mottled in appearance, of irregular density,

and are so movable that their position varies in successive skiagrams. Should difficulty arise, the examination should be repeated after a radio-opaque catheter or bougie has been passed into the ureter by means of a cystoscope (*Figs. 364, 365*). In many cases a stereoscopic examination of the area with a catheter in the ureter will show that the suspicious shadow is some distance from the ureter. A catheter may often be passed up

Fig. 364.—Skiagram of the pelvis, showing the shadow of a calculus in the ureter. (After M. B. Knapp.)

Fig. 365.—Skiagram of the pelvis, showing the shadow of a calculus in the ureter. (After M. B. Knapp.)

the ureter alongside and past a calculus in the duct, but a stereoscopic examination will show that the two are actually in contact with each other.

2. *A Concretion in the Appendix* may occasionally give rise to a shadow in the line of the right ureter, suggesting a calculus with very similar clinical symptoms. A further

Fig. 366.—Skiagram of the pelvis, showing the shadow of a calculus in the ureter. (After M. B. Knapp.)

Fig. 367.—Skiagram of a group of calculi, with an arrow occupies a position in the line of the ureter, but is shown to be distant from it by passing a radiographic catheter into the ureter. (After M. B. Knapp.)

examination with a radio-opaque catheter in the ureter will show that the shadow is extra-ureteric.

3. *Phleboliths in the Pelvis* are liable to be mistaken for ureteric calculi. They are usually multiple and are placed towards the peripheral areas of the pelvis, often about the level of the ischial spine. A stereoscopic examination with an opaque catheter in the ureter will differentiate them from calculi, though it may not be possible to distinguish

them from calcareous glands. It must not be forgotten that a calculus may be present in the ureter in addition to phleboliths. *Fig. 366* is an example of this, a single calculus being present in the ureter at the tip of the bougie, with the shadows of numerous phleboliths scattered elsewhere in the patient's pelvis.

Radiographic examination of the *vesical area* is required less frequently for calculi than is that of the renal or ureteric areas, owing to the ease of diagnosis of bladder conditions with the cystoscope. Occasionally, however, a shadow may be present in a pelvic radiograph which must be differentiated from that of a vesical calculus. The latter is usually rounded or oval, occupies a fairly central position in the pelvis, and may show rings of varying density owing to the deposition of layers of urinary salts of varying density (*Fig. 294*, p. 355). Occasionally one or more vesical calculi may form a shadow in a more lateral position in successive negatives, when a suspicion of their presence in a diverticulum in the bladder will arise. The diagnosis of this condition is discussed below. The following conditions may give rise to radiographic shadows in the pelvis:

1. Prostatic calculi
2. Calcification of a uterine fibroid
3. Opaque masses in a dermoid cyst of the ovary
4. Foreign bodies in the bladder
5. Urethral calculi.

Fig. 366.—Radiogram of a calculus in one ureter in contact with a ureteral catheter, together with shadows of several phleboliths not related to the catheter. (*Re. Br. Med. J.*)

Fig. 367.—Shadow of a tumour in the vesical area, due to calcified prostatic nodules. (*Re. Br. Med. J.*)

1. *Prostatic Calculi* may be single or multiple, but in the radiogram they occupy a position very low in the pelvis, often behind the shadow of the pubes (*Fig. 367*). They would not be seen by a cystoscope, but might be felt during the passage of any instrument through the prostatic urethra when the latter is ulcerated by the stone. They are palpable above and per rectum, either as a hard, inelastic nodule embedded in the prostate, or as a grating of multiple calculi on each other on pressure.

2. *Calcification of a Fibroid Tumour of the Uterus* gives a large, irregular shadow of varying but low degree of density. Bimanual palpation of a tumour moving with the uterus would point to the diagnosis.

3. *Ovarian Dermoids* may give rise to irregular shadows in the pelvis due to the formation of bone or teeth in the cyst. They may be present in young adult life, and a tumour would be palpated on abdominal or pelvic examination.

4. *Foreign Bodies* in the bladder may become so encrusted with urinary salts that a shadow like that of a calculus may be present. A variety of foreign bodies have been found in the bladder, either introduced by intent or by the accidental breaking off of a piece of catheter or the like. In some cases the shadow will show a central area of different density or even a metallic nucleus.

5. *Urethral Calculi* may be retained in the canal behind a stricture and enlarge *in situ*. They form a shadow in a radiograph below the pubic arch (*Fig. 368*).

Much assistance in the diagnosis of urinary disease apart from the presence of calculi may be obtained by means of radiography supplemented by methods used by the urologist. A good negative taken in a thin subject may show the outline and size of the kidneys so plainly that one of them may be demonstrated to be enlarged, whilst to the expert radiologist the degree of density of the shadow may indicate distention of the kidney by pus, or the irregularity of outline may give rise to a suspicion of malignant growth. Recently methods have been evolved by which more information may be gained—namely, by the injection of gas into the perirenal tissues or by the direct distention of the renal pelvis and ureter by radio-opaque solutions.

1. *Perirenal inflation* consists in distending the fatty tissue around the kidney with oxygen or carbon dioxide gas, it being claimed that by this method a more distinct outline of the kidney is obtained. It is found that carbon dioxide diffuses into the perirenal tissues more rapidly than oxygen does and that it is more rapidly absorbed. A hollow needle is passed into the loin until it is judged that the point has reached the perirenal fat, the depth of which varies greatly in different people. About 300 to 500 c.c. of gas are then introduced through the needle and an exposure made to X rays in the ordinary way. The outline of the kidney may be defined more clearly by this method, but its use is practically limited to stout patients in whom a renal growth is suspected, yet in whom

Fig. 368. Radiograph taken after inflation of the kidney with carbon dioxide gas. (Dr. J. M. Brown.)

Fig. 369. Pyelography: skiagraph of a normal renal pelvis distended with sodium bromide solution. The catheter passes into the upper calyx. (Dr. J. M. Brown.)

other methods of skiagraphy fail by reason of the fatness; unfortunately the inflation is painful and not free from risk.

2. The injection of radio-opaque solutions into the renal pelvis and ureter, combined with radiography (*pyelography* and *ureterography*), has a much wider application and renders much more precise information than can be obtained by the perirenal inflation method. In the earlier work in this subject, solutions of collargol, silver iodide, and thornum nitrate were used, but were found unsatisfactory owing to the pain caused by the solutions or to the occasional toxic symptoms produced by them. In recent years sodium bromide in 20 per cent solution has been used extensively instead; it is not irritating, is not toxic, and, moreover, yields a dense shadow to the X rays. For pyelography a ureteric catheter is passed by means of the cystoscope to the renal pelvis; the solution of sodium bromide is injected very slowly by means of a small syringe or allowed to run in by gravitation until the patient begins to feel discomfort in the loin, an accurate measure of the amount of fluid injected being recorded. The pelvis of the normal kidney will hold an average of 6 c.c. before pain is produced. A skiagraph is taken immediately, when an exact outline of the renal pelvis and calices is displayed as a dense shadow (Fig. 369). In cases of renal distention a much larger amount of sodium bromide can be injected before pain is produced. In these cases it is better in practice to take a succession of radiograms with the increasing amounts of fluid injected rather

than to await the onset of pain. Thus if in an examination it is found that the patient feels no discomfort after the injection of about 8 c.c., the injection should be stopped and a radiograph taken: further injection is then made and a second or even a third negative exposed. In renal distention the first radiograph may show only a blurred shadow from

Figs. 370, 371. Pycelographs of a case of pelvic hydronephrosis in successive stages of distention. In *Fig. 370*, 2 c.c. had been injected, and in *Fig. 371* this had been increased to 6 c.c. (*Clin. Dr. Knorr*.)

the dilution of the sodium bromide solution with the fluid in the renal pelvis, but the subsequent negatives will show the extent of the distention and whether the stress is thrown on the renal tissue or on the pelvis (*Figs. 370-372, 376*).

It is essential that this examination be conducted without the administration of an anæsthetic so that the patient can indicate when the discomfort due to the distention of the renal pelvis begins. Frequently the patient is able to affirm that the pain produced by the injection is exactly similar to that experienced during his previous clinical attacks—often a valuable point in diagnosis. Occasionally a calculus which has only yielded a faint shadow in a skiagram is shown much more distinctly after an injection of sodium bromide around it. Commencing dilatation of the renal pelvis, a difference in the normal angle at the uretero-pelvic junction, or kinking of the upper ureter can be identified readily (*Figs. 373-375*).

Fig. 372. Pycelograph of a renal hydronephrosis with dilatation of all calyces. (*Clin. Dr. Knorr*.)

The determination of a normal renal pelvis by radiography has also aided the diagnosis in many cases of doubtful abdominal tumours in which the clinical data have cast a suspicion of renal disease. There may be doubt as to whether a tumour palpable in the abdomen and causing pain in the loin is a renal tumour or whether it originates in the colon, gall-bladder, pancreas, or suprarenal gland. Examination by pycelography may demonstrate a normal renal pelvis which would in many cases exclude any disease of the kidney. In a recent case under my care, a patient, age 47, complained of pain in her left loin, where a rounded tumour presenting the characters of a renal swelling was

felt. She gave a history of slight hæmaturia and the urine contained a small amount of albumin and pus. To cystoscopic examination there was subacute cystitis: the ureteric orifices appeared to be normal, and the urinary efflux from each was stained a deep blue colour within five minutes of an intravenous injection of indigo-carmin. A pycelographic

examination of the left kidney showed that the renal pelvis and calices were small and normal, so that the diagnosis of renal disease was negatived. Abdominal exploration revealed a carcinoma of the colon near the splenic flexure, for which resection was performed. In another case a mesenteric cyst was thought to be a hydronephrosis until a

Fig. 373. Pyelogram showing normal kidney with small renal pelvis and calices. (By Dr. J. H. H. H.)

Fig. 374. Pyelogram showing commencing dilatation of the renal pelvis. (By Dr. J. H. H. H.)

pyelograph proved the kidney to be normal. Thus pyelography may be used not only in the diagnosis of a renal lesion, but also as a means of excluding renal disease in cases in which the diagnosis may be difficult.

To obtain a radiogram of the ureter, it is advisable to pass the ureteric catheter only a short distance into the ureter before making the injection of sodium bromide. In this way any dilatation or deviation from the normal line of the ureter is demonstrated, whereas the passage of the catheter along the whole length of the canal might straighten out the latter. In some cases the passage of the catheter may be obstructed in the ureter; in these the injection should be made with the catheter *in situ*, when the fluid may find its way past the obstruction and radiography may show a dilated or tortuous ureter with dilatation of the pelvis of the kidney. Fig. 375 was obtained in this way from a case of ureteric obstruction causing persistent pain due to the fixation of the ureter in the scar of an operation for nephropexy.

Occasionally a radiographic picture of the bladder is required to determine the size of a diverticulum, the vesical opening of which has been found on cystoscopy. For this purpose it is advisable to use a weaker solution of sodium bromide, namely 7 to 10 per cent, as a solution of greater strength is liable to cause considerable pain, especially if the bladder be inflamed. Radiograms are then taken in both the antero-posterior and the lateral planes; it is also of advantage to repeat the exposures after the patient has voluntarily voided the vesical contents, when the diverticulum may be seen to remain filled with the solution.

Fig. 375. Pyelogram showing kinking of the upper ureter. The kink was due to the scar of a former renal operation, and the patient had much renal pain from commencing renal distention. (By Mr. W. A. Cuthbert.)

A kidney may be enlarged but yet not palpable from the fact that it is either wholly above the costal margin or obscured by the liver or the thick abdominal walls of the

patient. On the other hand a kidney may be so diseased as to be functionless and shrunken, when it cannot be felt; but the remaining organ may be enlarged in a compensatory degree and may be distinctly palpable. One must remember the danger of regarding an enlarged kidney as the diseased organ when it may in reality be the only functioning one. Aching pain may be present on the functional side, as a reno-reflex pain from the disease on the other side. The kidney of normal size and position is not palpable from the abdomen, or on bimanual examination with one hand on the loin; but, in a thin subject, the lower pole may be felt to descend between the hands on the patient's taking a full inspiration; if, therefore, a kidney can be felt easily on bimanual examination, it is either unduly mobile or enlarged. It is often difficult to say if a kidney that is movable is also enlarged to a slight degree; and a kidney which was thought clinically to be enlarged has often been found to be of normal size when exposed; this is in part due to the thick coverings of the abdominal wall, or to the amount of fatty tissue surrounding the organ.

If the kidney is definitely enlarged, it remains to determine the nature of the enlargement; in this one is guided, not only by the physical characters of the tumour present, but also by other symptoms that are associated with it, more especially, perhaps, by the altered characters of the urine. The kidney may be enlarged only slightly, as in tuberculosis, pyelonephritis, commencing hydronephrosis, or carcinoma; or may be enlarged to a considerable degree in polycystic disease, hydro- or pyonephrosis, and in some forms of malignant growth. From the physical examination of the enlarged organ it is often possible to say that the swelling is fluid or solid in nature, but it is seldom that a true diagnosis of the lesion can be made from palpation of the kidney alone. In the following diseases in which renal enlargement is usually present, the diagnosis must be arrived at by the consideration of associated symptoms.

In *renal tuberculosis* the disease occurs in a miliary or in a caseous form. Miliary tuberculosis occurs as a part of a general tuberculosis, usually in children, is bilateral, and causes no tumour. The caseous variety occurs as a primary disease in one kidney, in which one or several foci may be present. These enlarge and soften to form a tuberculous abscess, which invades the medullary tissues, to open eventually and discharge its contents into the renal pelvis. The kidney is enlarged and tender, and there are persistent pyuria and hæmaturia in small amount. The lining membrane of the ureter is quickly invaded by the tuberculous process, becoming thickened and infiltrated, and at the same time shortened, so that cystoscopically the ureteric orifice is seen to be drawn upwards (*Fig. 573*, p. 717). An early symptom of renal tuberculosis is increased frequency of micturition, even before the bladder has become infected in the downward progress of the disease. The ureter may be felt to be thickened per rectum or per vaginam, or other tuberculous foci may be found in the prostate, vesiculae seminales, or testes in the male. A thorough search should be made for tubercle bacilli in the urine.

In *pyelonephritis* the kidney may be slightly enlarged, together with renal pain, pyuria, and general malaise. Pyelonephritis is usually bilateral, and due to some infective or irritative lesion in the lower urinary tract, symptoms of which are usually obvious (*Fig. 574*, p. 715). Bacteriological examination by culture of a catheter specimen of urine is almost essential to the diagnosis.

Malignant tumours of the kidney give rise either to an irregular nodular enlargement of the kidney, or to a general, uniform, solid tumour. There is usually aching pain in the loin, with intermittent attacks of profuse hæmaturia, the latter occurring as soon as the growth has infiltrated the renal pelvis. The bleeding may be so profuse that clots are formed in the renal calices, pyramidal in shape, which in their passage down the ureter give rise to typical renal colic. Long worm-shaped clots from formation in the ureter may also be present. The malignant tumours found in the kidney are of several varieties, and their origin and exact pathological nature have given rise to much discussion in recent years. The true carcinoma and sarcoma exist, but are very rare, forming but a small percentage of the malignant renal tumours. They give rise to renal enlargement and intermittent hæmaturia, are usually extremely malignant, and are accompanied by early metastases. The more common type of renal tumour in the cortical portion of the kidney the hypernephroma was formerly supposed to arise in small aberrant areas of suprarenal tissue which are frequently found in this situation. Recent observers maintain

that these tumours arise from the renal elements. The tumours commonly arise in the upper pole of the kidney, are of yellow or brown colour, and are usually fairly well defined from the renal tissues. Microscopically, their structure is similar to that of the suprarenal gland, and their metastases are of the same nature. They were formerly described as angiosarcoma, alveolar sarcoma, endothelioma, or carcinoma, but are now classified under the term hypernephroma. They form a comparatively slowly-growing tumour of the kidney, and give rise to less severe symptoms than the true sarcoma or carcinoma. There is aching in the loin, and enlargement of the kidney may be found on examination, but at first the symptoms are slight. Hematuria occurs without any apparent exciting cause, and there may be renal colic from the passage of clots down the ureter; the tumour may be of fair size before any hematuria is noticed.

Another form of malignant tumour that occurs in the kidney is that which is supposed to arise from embryonic tissues, and to which the name of embryoma has been applied. These tumours are formed of striated muscle (rhabdomyoma) or of mixed tissues, such as striated and non-striated muscle, cartilage or bone, and epithelial structures in tubular or glandular form. They grow in the renal tissues, expanding the latter to form a spurious capsule. They occur most frequently in children, and hematuria is infrequent.

Thus, the occurrence of a renal tumour, accompanied by intermittent attacks of hematuria, especially if profuse, should always give suspicion of renal growth in an adult. Renal tuberculous and calculus both may give rise to renal enlargement, but the hematuria is seldom profuse; with calculus, the hematuria is often brought on or increased by exertion, whereas with growth it may come on at any time, even during rest. At the same time, it should be remembered that both profuse hematuria and renal enlargement may arise from a vesical tumour which obstructs the normal flow of urine from the ureteric orifice; in all cases, therefore, a cystoscopic examination should be made before any operative measure is carried out. The rapid development of a *varicocele*, especially on the right side, is a point significant of renal growth.

Hydronephrosis and *pyonephrosis* form definite enlargements of the kidney, which may attain a large size. The tumour is oval or rounded, smooth, and gives a sense of tenseness or elasticity, whilst occasionally distinct fluctuation may be obtained. Pycelography assists the diagnosis very materially

(p. 440 et seq. and Figs. 370-76). A hydronephrosis occurs when there is a partial ureteric obstruction, or in cases of repeated attacks of temporarily complete obstruction to the ureter. Bilateral hydronephrosis may also arise from the back-pressure due to any obstruction of the normal passage of urine from the bladder. Hydronephrosis is usually unaccompanied by pain or hematuria; but the tumour may show marked changes in size, from the varying character of the lesion producing the obstruction; thus, if the ureter be wholly blocked, the tumour will increase in size and become more tense; whilst if the obstruction be partially relieved the tumour will diminish, synchronously with the passage of a larger quantity of urine of low specific gravity. The presence of any obstruction to the normal flow of urine from the kidney predisposes to the onset of infection of the kidney by micro-organisms, so that a hydronephrosis may become converted into a pyonephrosis, or the latter may arise from the obstruction to the ureter of a kidney already the seat of pyelitis. The physical examination of a kidney distended with urine or with pus shows practically no difference between them, but with pyonephrosis other indications are usually present to assist the diagnosis. Examination of the urine will reveal the presence of pus at some time, although, if the ureter is wholly obstructed at

Fig. 376. To illustrate pycelography, Col. Lantz has been introduced into the right ureter and renal pelvis after ureteral catheterization. The case was in a girl female with right-sided hydronephrosis, the result of calculous disease. Two stones had been removed from this kidney a year previously, at which time the pycelographic appearances were practically the same. (By Dr. C. Thurston Thomas.)

the time of examination, pus may be absent if the other kidney and the bladder are normal. If, however, the ureter is blocked only partially, pus will be found in the urine; in the intermittent form, pus may be present in large quantities at intervals coinciding with the decrease in the size of the renal tumour. With pyonephrosis, also, there will be the general evidence of suppuration, namely, raised temperature, sweating, pallor, and often diarrhœa. The most frequent causation of pyonephrosis is renal calculus, so that a careful inquiry into the history of the case for symptoms of calculus may give important indications, and X-ray examination may be of service (p. 440 et seq.) unless the stone has been passed. Very occasionally palpation of a kidney enlarged from calculous disease will give rise to distinct crepitation from the friction of one stone upon another.

A *serous* or *hydatid cyst* of the kidney may give rise to a tumour in the loin exactly resembling a hydronephrosis, and would usually be diagnosed as such. The discovery of hooklets (*Fig. 76, p. 65*) or hydatid elements in the urine, or in the fluid aspirated from a renal cyst, will point to the nature of the disease.

Polycystic disease of the kidney may occur in children or in adults, and forms a tumour which is commonly bilateral, though that of one side may be larger than the other. In adults the disease causes practically no trouble, except the presence of the tumour, in the early stages; but later, symptoms of renal inefficiency develop. The tumour gives the usual physical signs of a renal enlargement, and may attain a great size on both sides. There may be aching pain in the loins, and, occasionally, marked hæmaturia. The urine is of low specific gravity, is increased in amount, and in the absence of blood often contains a small amount of albumin. The disease is usually accompanied by arteriosclerosis and raised blood-pressure. The character of the urine and the bilateral renal tumour are usually sufficient data upon which to form a diagnosis; but with unilateral tumour, as occasionally occurs, the diagnosis is very difficult. A hydronephrotic or pyonephrotic kidney may give evidence of fluctuation which will not be obtained with a polycystic kidney.

R. H. Jocelyn Swan.

KNEE-JERK, ABNORMALITIES OF THE.—Before discussing the abnormalities of the knee-jerk it is desirable to say a few words concerning the methods employed for eliciting this valuable physical sign, and what may be considered to be its normal variations.

It is essential, if mistakes are to be avoided, to test the knee-jerk with a suitable instrument. The fingers, or the edge of a hand or of a book, are unsatisfactory. Several percussors are made for the purpose, the best being a proper knee-jerk hammer, though it may be more convenient to use a wooden stethoscope with a moderately heavy ear-piece surrounded by a thick indiarubber ring. The patient should be either sitting or lying

1. If seated in a chair, he may be directed to cross one knee over the other, or, better
2. place both feet on the floor as far away from him as is possible, so long as the whole sole of each is in contact with the ground. If the patient is in bed, he should lie flat on his back, and be told to allow the observer to move his legs without resistance. The latter then flexes the knee by grasping the thigh above the joint and raising it until an obtuse angle is formed by the popliteal space, the foot resting on the bed. The position of the manipulator's hand will enable him to detect whether the quadriceps and hamstring muscles are sufficiently relaxed. In either position a tap on the patellar tendon will provoke a contraction of the quadriceps extensor muscle, which will extend the leg on the thigh, and may be seen or felt even if it fails actually to move the leg. In the case of small children or infants it is advisable to stand at the end of the bed and to grasp the ankle with the left hand; the knee can then be flexed easily by pushing the foot towards the patient, and, at the moment when the limb feels relaxed, a tap on the patellar tendon be given with the instrument in the right hand. If difficulty is found in making an adult relax his limb in any of these positions his attention should be directed to carrying out some other voluntary movement, such as pulling apart his grasped hands while he looks at the ceiling; this is known as 'reinforcement'.

The Normal Knee-jerk. It is impossible to define a normal knee-jerk, because the extent of the reaction varies much in individuals and much in the same person at different times. Absence of the knee-jerk indicates an abnormality, and must be regarded

as pathological. Inequality of the jerk on the two sides must also be regarded as strong evidence of some organic morbid condition.

Abnormalities. The knee-jerk may be exaggerated, diminished, or lost.

The knee-jerk is *exaggerated* when the reflex arc which governs the tone of the quadriceps muscle is insufficiently inhibited or controlled by the higher nervous centres. This occurs under two chief conditions, one of which constitutes a functional, the other an organic, loss of control.

Functional loss of control occurs whenever the general health or nervous tone of the patient is below par. Exaggeration of the knee-jerk may therefore be met with in *almost any constitutional ailment*, and is nearly always to be observed when a person is seriously out of health. For instance, a phthisical patient, a case of chronic renal disease, a convalescent from enteric fever, or a neurasthenic, may present very brisk jerks, and their presence may only be looked upon as an indication of a general loss of nervous tone. This fact emphasizes the necessity for never being satisfied with an examination of the knee-jerk alone in attempting to diagnose the condition of the nervous system. The examination of the knee-jerk must at least be supplemented by that of certain other reflexes, the most important of which are the abdominal and plantar. If exaggerated knee-jerks are associated with normal abdominal reflexes and with the flexor type of plantar response, and if the knee-jerks are approximately equal on the two sides, it may be assumed, with some exceptions, that the exaggeration is due to a functional loss of control over the reflex arc. If, on the other hand, the abdominal reflex is absent and the plantar response is of the extensor type the exaggeration of the knee-jerk is due to some organic change in the cells of the motor area of the brain or in the pyramidal tracts which are made up of the axonal processes of those cells. Exaggeration of the knee-jerk due to organic disease is always, or nearly always, associated with other reflex changes, and particularly with the extensor type of plantar response. Frequently, but not invariably, these two signs are supplemented by the presence of ankle-clonus, by a spastic condition of the lower extremities, and by a loss of voluntary control over the vesical and rectal sphincters.

When the pyramidal tract is affected equally on both sides the jerks will also be exaggerated equally; but if, as in hemiplegia, one pyramidal tract is more diseased than the other, there is a corresponding difference in the knee-jerk on the two sides, that of the paralysed leg being brisker than that of the sound limb. Inequality of the knee-jerk is also observed in certain cases of *general paralysis of the insane*, for the same reason.

A very brisk knee-jerk is sometimes associated with a phenomenon which goes by the name of patellar clonus. With the limb resting relaxed and fully extended on the bed the patella is sharply pressed towards the foot, with the result that clonic contractions of the quadriceps are provoked and continue as long as the pressure is sustained. The presence of well-sustained patellar clonus is generally indicative of organic disease affecting the crossed pyramidal tracts.

The knee-jerk may be *diminished* as the result of some pathological processes similar to those which abolish the jerk. On the other hand, owing to the natural variations in the activity of the reflex, it is often difficult to be sure that the sluggish character of a knee-jerk is of pathological origin unless there is evidence to show that it had been obtained previously with greater facility.

The knee-jerk is *lost entirely* in a very small percentage of perfectly normal individuals, some of whom appear to have had no knee-jerks from the start; but, upon the whole, complete absence of knee-jerks, even when attempts have been made to obtain them after reinforcement, indicates organic disease of the nervous system, and therefore is evidence of some pathological process. The conditions under which the knee-jerk is lost may be classified in the following manner:

1. Affections of the quadriceps extensor muscle, as in the myopathies.
2. Affections of the afferent path of the reflex arc, as in cases of tabes in which the lumbar region of the spinal cord is involved.
3. Affections of the anterior horn cells, such as occur when myelitis involves the third and fourth lumbar segments of the cord.
4. Affections of the efferent fibres in the anterior crural nerve innervating the quadriceps muscle, as in some forms of peripheral neuritis.
5. In complete transverse lesions of the spinal cord above the lumbar enlargement.

This is usually the result of a dorsal myelitis, or of a fracture-dislocation of the vertebral column with severe injury to the cord : in these patients the tendon jerks will re-appear after an interval of three or four weeks provided that there is no septic complication in the form of bedsores, cystitis, or pyelonephritis.

6. When the intracranial pressure is greatly increased, particularly in cases of intracranial tumour, and more especially when the tumour occupies the posterior fossa of the skull : also immediately after a gross cerebral hæmorrhage.

It should be noted carefully that the absence of the knee-jerk in most cases affords evidence of some lesion of the structures which constitute the reflex arc, on the integrity of which it depends. It is a localizing sign, not necessarily a sign of some particular disease. For instance, it is quite possible for patients suffering from tabes to retain their knee-jerks so long as the morbid process has not involved the lumbar region of the spinal cord, or one knee-jerk may disappear before the other. For the same reason the jerk may be present in certain cases of acute poliomyelitis, or one may remain when the other has been lost.

It is also desirable to point out that the abolition of the knee-jerk may be the *only* indication of any affection of the nervous mechanism. For example, the knee-jerk is often lost after an attack of *diphtheria*, even when there is no evidence of paralysis of the leg muscles or of any sensory loss in the lower extremities. Another instance of the same kind is afforded by many cases of *lobar pneumonia*, especially in children, in which the pneumo-toxin is sufficiently poisonous to interfere with the sensitive patellar reflex without producing other signs of disturbance of the nervous system. In *diabetes mellitus* the knee-jerks may be absent without any further signs of peripheral neuritis developing.

Attention has been drawn to the occasional absence of knee-jerk in cases of intracranial tumour. The explanation of this is not very clear, but reference may be made to the great variability of this phenomenon from time to time. At one examination the knee-jerk is obtained ; at another, a few hours later, it is lost, perhaps to return on the following day. This ebb and flow of the knee-jerk is highly characteristic of increased intracranial pressure, and is rarely found under other conditions. Immediately following a *cerebral hæmorrhage* associated with hemiplegia it may be impossible to elicit the knee-jerk in the paralysed leg, whereas a few days later the knee-jerk on this side may be found not merely present, but brisker than that on the sound side.

Two other forms of abnormal knee-jerk deserve brief reference. One of them is what is sometimes called the *choric knee-jerk*. In many cases of chorea, when the leg is extended on the thigh as the result of tapping the patellar tendon, it is held in that position for an appreciable length of time before relaxation takes place and the foot falls to its former position. In *myasthenia gravis* it is sometimes, but only rarely, possible to tire out the knee-jerk. A ready response is obtained at first, but rapid repetition of the test leads to abolition of the reflex excitability, which quickly recovers itself after a short rest.

LEGS, SWOLLEN.—(See EDEMA, p. 511.)

LEUCOCYTOSIS denotes an increase above the normal of the number of leucocytes per c.mm. of blood. The point at which the increase is to be called leucocytosis is arbitrary, for whereas 5000 per c.mm. is regarded as the average in health there are considerable variations during the day, either in relation to digestion, exercise, or what not, and the same person who at one time of the day may have 5000, may at another have even as many as 14,000 per c.mm. If the differential leucocyte count remains normal,

no total leucocyte count less than 15,000 per c.mm. can be regarded as abnormal, and it is not until the figure reaches 20,000 or more that much stress can be laid upon it. The numbers tend to be higher in children and in pregnant women than in other healthy individuals. From a clinical point of view there are only two main groups of conditions in which the existence of leucocytosis is really of diagnostic importance, namely: (1) In cases of splenomedullary, lymphatic, or mixed leukaemia, the differential diagnosis of which is discussed under ANÆMIA (p. 32); and (2) In connection with infective processes, such as suppuration, pneumonia, sapræmia, or septicopyæmia.

There are many maladies in which moderate leucocytosis may occur, but in which the behaviour of the leucocytes themselves is of little diagnostic significance. Thus, whether there is or is not any leucocytosis makes little or no difference in the diagnosis of many conditions in which the number may be anything from 5000 to 20,000 per c.mm., for instance acute rheumatism, scarlet fever, myxœdema, intestinal obstruction, diphtheria, cholera, fetid bronchitis, bronchiectasis, urethritis, acute follicular tonsillitis, whooping-cough, carcinoma, sarcoma, rabies. In all of these, and probably in many others, whereas many cases show no leucocytic change at all, a certain proportion exhibit leucocytosis. If there were a universal rule, either that there was leucocytosis or was not, the fact might be used in differential diagnosis: for instance, the occurrence of leucocytosis in scarlet fever might be used as a point in distinguishing it from measles, in which leucocytosis is rare: but it is just possible that there may be a leucocytosis in a case of measles, and it is more than possible that scarlet fever may present no leucocytosis, so that, whereas the general rule is to the contrary, it is not so constant as to be a safe ground upon which to make a differential diagnosis. It can only be said, broadly speaking, that whereas leucocytosis is not uncommon in the conditions already enumerated, it is upon the whole not common in measles, malaria, typhoid fever, typhus fever, influenza, small-pox, mumps, and tuberculosis other than caseous bronchopneumonia, secondary infected phthisical cavities, or tuberculous meningitis.

It is stated that certain *drugs* may produce leucocytosis, though careful experiments with some of them have by no means always confirmed this. Succinic acid, protargol, and essential oils such as turpentine, peppermint, or cinnamon, are examples of those said to produce slight leucocytosis. After severe *loss of blood*, such as may result from excessive hæmatemesis, venesection, post-partum hæmorrhage, and the like, the leucocytes may rise in a comparatively short time to over 15,000, and perhaps to over 20,000 per c.mm.

It is clear, therefore, that when so many conditions may lead to leucocytosis, its importance is much diminished as a means of differential diagnosis. One may say, however, that unless there are other clinical indications to the contrary, a definite leucocytosis of 20,000 or more—the figure sometimes reaching even 50,000 or 60,000—together with a relative increase in the polymorphonuclear cells from their normal 65 per cent to 75, 80, 85, or even 90 per cent of all the leucocytes present in the blood, is considerable evidence of there being *suppuration* somewhere. It is worthy of notice that in a suppuration which produces leucocytosis with a relative increase in the polymorphonuclear cells, the pus requires to be confined under pressure, for instance in an appendicular abscess, an abscess of the liver, empyema of the gall-bladder, suppurative pyelophlebitis, infective cholangitis, perineal abscess, pyosalpinx, suppurating ovarian cyst, thoracic empyema, abscess of the lung, cerebral abscess, subcutaneous or pyæmic abscess, an unopened whitlow, an infected thrombosed vein, or suppurating lymphatic glands. When an abscess which has hitherto been associated with leucocytosis is opened the number of leucocytes in the blood falls quickly to normal: there is little or no leucocytosis in conditions in which pus is not under pressure, for instance in cases of impetigo and other forms of pyoderma, superficial gangrene of the skin, suppuration connected with opened hip-joint disease or psoas abscess, and so forth. It is probably on this account that fungating endocarditis often produces a slight, but hardly ever any considerable, leucocytosis; the same applying to pyelitis, pyonephrosis, and pyelonephritis, in all of which, if there is free drainage through the ureter, leucocytosis is absent, whilst if there are abscesses in the kidney substance the leucocytosis may be considerable. Gangrene of the lung is another instance of the same kind, for there may be extensive gangrene without leucocytosis if there is free expectoration: whilst if the gangrenous tissue is prevented from escaping, leucocytosis may result.

Erysipelas is an exception to the rule that superficial suppuration does not produce leucocytosis, for here considerable increase in the leucocytes is common.

Amongst diseases in which, though they are not in the ordinary sense suppurative, leucocytosis is the rule, are *acute meningitis* and *pneumonia*. Unfortunately, all forms of acute meningitis, whether tuberculous, suppurative, or meningococcal, lead to more or less leucocytosis, so that this point cannot be made much use of in the differential diagnosis between them: but upon the whole the greatest leucocytosis, up to 40,000 or more, is to be expected in the acute cerebrospinal form. The fact that pneumonia, whether of the lobar or lobular type, produces leucocytosis with a relative increase in the polymorphonuclear cells more often than not, makes it impossible to rely upon this point in determining whether an empyema is developing after the lung inflammation, unless it is known that up to the time of the crisis there was only a moderate leucocytosis, and that after a continuance of the fever, or a recurrence of it after the crisis, there is a greater leucocytosis, with a still further rise in the relative percentage of polymorphonuclear cells. When there has been no pneumonia, and when the physical signs are such as to suggest fluid in the chest, it is to some extent helpful to know that acute pleurisy, with effusion of the type sometimes spoken of as 'simple', shows little leucocytosis, whereas empyema nearly always produces a considerable leucocytosis of the polymorphonuclear type.

The value of the knowledge that there is leucocytosis when a given case has been hitherto regarded as one of some disease not associated with leucocytosis is obvious (see LEUCOPENIA below): thus, typhoid fever may have been diagnosed in a case of obscure pyrexia in which the existence of polymorphonuclear leucocytosis indicates that the diagnosis of typhoid fever is wrong, and that there is really deep-seated suppuration, such as an appendicular abscess, a pyosalpinx, or unsuspected dental or tonsillar abscess with prolonged pyrexia. Another similar example of the possible value of this in differential diagnosis is in distinguishing malaria, in which there should be no leucocytosis, from hepatic abscess, in which leucocytosis is the rule.

There is a special form of leucocytosis which may be extremely misleading, and this is a state of affairs termed '*symptomatic leukaemia*'. The patient's blood may present an almost typical picture of leukaemia, more often of the lymphatic than of the myelogenous type, and yet, though death may result, there is more often complete recovery and the blood picture returns entirely to normal. This kind of thing could escape recognition altogether if routine blood examinations were not made: but it has been met with under varied and various circumstances, generally as a sequela of some recognized malady such as *scarlatina*, *small-pox*, *mumps*, *whooping-cough*, *congenital syphilis*, *acute cervical adenitis*, *acute sepsis* such as a *chilloæ*. The leucocytes may rise to high figures such as 80,000, 120,000, 160,000 per c.mm., and over 70 per cent may be mononuclear lymphocytes, so that it may be extremely difficult at the time to say that the patient is not going to die of leukaemia: nevertheless, complete return to health may ensue, and although the only means of settling the diagnosis it is important that the possibility of symptomatic as distinct from ordinary lymphatic leukaemia should not be overlooked. Considerable lymphocytic leucocytosis may accompany *Kaposi's disease* (pigmentary meso-sarcomatosis of the face and skin). Symptomatic myelogenous leukaemia is rarer, and it is more often associated with malignant disease than with recoverable maladies, but occasionally one meets with cases of carcinoma of the penis, stomach, or other organ, with secondary deposits in various organs, presenting a leucocytosis of 100,000 or more, with myelocytes to the extent of 10 per cent or more of all the leucocytes present. These cases might be regarded as examples of intercurrent leukaemia, as distinct from symptomatic leukaemia: but the diagnosis depends upon full knowledge of all the details of the case.

Herbert French.

LEUCOPENIA denotes the presence of a smaller number of leucocytes per c.mm. of blood than normal. When there are less than 5000 leucocytes per c.mm. one may call the condition leucopenia. There are a large number of affections in which this occurs, in most of which the fact is of little, if any, diagnostic importance. It may result from simple *starvation*, either voluntary, or due to stenosis of the œsophagus or other similar lesion. It is the rule in most *chronic intoxications*, particularly those which result from

plumbism or poisoning by *mercury, arsenic, ether, alcohol, trinitrotoluol, morphia, heroin, omnopon, chloral, or cocaine*. It is to be found in certain of the *severe anemias*, more particularly *pernicious anemia, aplastic anemia*, and some cases of *lymphadenoma*, particularly in the later stages. *Acute miliary tuberculosis* is often associated with leucopenia, and so also is *tuberculous peritonitis* in more cases than not.

The chief diagnostic importance of leucopenia is in connection with two diseases in particular, namely, *typhoid fever* and *malaria*. In the former there is leucopenia almost from the beginning, and cases are not few in which, during the earlier days of the illness, before Widal's reaction could be positive, typhoid fever has seemed probable until the discovery of leucocytosis instead of leucopenia has suggested suppuration rather than typhoid, the pus being discovered subsequently perhaps in the pelvis in connection with a pyosalpinx, or in an appendicular abscess, or the like. The differential leucocyte count may also assist in the same direction, for the leucopenia of typhoid fever is associated with a relative increase of the smaller lymphocytes and diminution of the polymorphonuclear cells, whilst with suppuration the reverse is the case. Leucopenia will not serve to distinguish between typhoid fever on the one hand, and either general tuberculosis, influenza, or malaria upon the other; but granted that there is a pyrexial illness suggestive of typhoid fever, the occurrence of leucopenia with a relative increase in the small lymphocytes helps considerably in confirming the diagnosis days before the Widal's reaction would be positive. The leucopenia persists unless perforation or other complication leading to pus formation supervenes.

Malaria is generally associated with a reduction of the total number of leucocytes per c.mm. down to perhaps 4000, 3000, or even less. Associated with this leucopenia there is relative increase, not in the small lymphocytes as in typhoid fever, but in the large hyaline leucocytes; the association of these two things together in a patient whose history points to the possibility of malaria may assist considerably in clinching the diagnosis, and it may be of particular value in cases in which quinine has been administered so that the most conclusive proof of the nature of the complaint, namely the discovery of the malarial parasites in blood-films, is not for the moment possible. One difficulty which is not at all uncommon in the tropics is to decide between malaria on the one hand and abscess of the liver upon the other. Leucopenia and a relative increase in the large hyaline corpuscles strongly favours malaria, whereas an abscess would cause leucocytosis and a relative increase in the polymorphonuclear cells. It is not malaria alone amongst tropical diseases, however, that produces leucopenia, for the latter is also met with in visceral leishmaniasis (kala-azar), dengue fever, and in undulant fever in its later stages.

Visceral leishmaniasis causes progressive anaemia of the chlorotic type, more profound in the infantile than it is in the adult cases; there is a great and constant reduction in the total leucocytes; the polymorphonuclear cells are much diminished, the lymphocytes and large mononuclear cells being thereby relatively but not absolutely increased; the coarsely granular eosinophil cells often disappear entirely. The diagnosis is established by the discovery of Leishman-Donovan bodies (*Fig. 605*, p. 779) in spleen or liver pulp obtained by puncture.

Dengue causes no true anaemia, but leucopenia (3000 to 5000 cells per c.mm.) is nearly always present, appearing as early as the first or second day of the disease. The polymorphonuclear cells are often reduced below 40 per cent, so that the small lymphocytes appear relatively increased.

Undulant fever may cause a slight leucocytosis at first, but as the disease progresses a secondary anaemia develops with leucopenia, the decrease involving the polymorphonuclear cells more than the lymphocytes. Blood cultures and the agglutination test are the most important aids to the diagnosis.

It is remarkable that whereas in white people *pneumonia* generally causes a leucocytosis, or at any rate not a leucopenia, in *negroes* it may be associated with leucopenia down to less than 1000 per c.mm.; the reason for this racial difference is obscure, but it is associated with a bad prognosis as a rule.

Another very important cause of leucopenia is the effect of radiation either by *radium* or by *X rays*, when the radiations are continued over a period measured in weeks or months rather than in days; there is a diminution in all forms of leucocytes, and the total numbers per c.mm. may fall to 2500, 2000, or even 1000. If the radiations are continued, severe

anæmia supervenes as well, and the patient dies of a condition very similar to aplastic anæmia; this state of affairs is spoken of sometimes as radium disease or X-ray disease, as the case may be.

Herbert French.

LEUCORRHEA.—(See DISCHARGE, VAGINAL, p. 231.)

LIMBS, PAIN IN THE.—(See PAIN IN THE LIMBS, p. 568.)

LIMPING.—(See GAIT, ABNORMALITIES OF, p. 313.)

LIMPING IN CHILDREN. (See also GAIT, ABNORMALITIES OF, p. 313.) Limping in a child may be present from the time it first begins to walk, or it may develop in one who has previously walked normally. In either case it may be due to pain, to deformity, to some form of paralysis, to mimicry, to bad habit, or to two three or more of these combined. Apart from absolutely acute affections, such as suppurative osteomyelitis of the tibia, the one condition that it is most important to diagnose or exclude as the cause is tuberculous disease of the hip-joint, for limping may be the earliest and only sign of this malady, in its most curable stage if proper treatment by complete and prolonged rest is adopted forthwith. The next most important causes, generally recognized with greater ease, are tuberculous disease of the knee, the ankle, or the tarsus. Most other lesions need little discussion, for their nature is generally obvious from the history or upon careful examination of the leg and foot. Any painful or deforming affection of the lower limb, from toes to spine, may lead to limping, and one may enumerate the following:

1. Causes affecting the Foot or Ankle, and associated with Pain in the Foot:

Ill-fitting boots, especially those which are too short	Tuberculous dactylitis
Chilblains	Tuberculous disease of the tarsus
Corns	Tuberculous disease of the ankle
Whitlow of a toe	Rheumatic 'growing pains'
Blister	Still's disease (p. 472)
Abrasion of the skin on any part of the foot	Suppurative arthritis in the ankle or foot
Injury by a crush, blow, kick, sprain, fracture	Peliosis rheumatica with hæmorrhage into
Foreign body, such as a thorn or a needle	Hæmophilia the ankle
Rubbed heel	Embolism (infective endocarditis)
Inflammation of the bursa beneath the tendo Achillis	Morton's disease (metatarsalgia).

2. Causes affecting the Foot or Ankle, and associated with Deformity rather than with Pain:—

Talipes varus	Talipes calcaneus	Hammer toe
Talipes valgus	Talipes equino-varus	Hallux erectus
Talipes equinus	Talipes calcaneo-valgus	Flat-foot.

3. Causes affecting the Calf:

Leggings or gaiters that are too tight	Green-stick fracture of tibia or fibula
Garters that are too tight	Sarcoma of the tibia
Bruising	Sarcoma of the fibula
Infantile paralysis, with atrophy of the calf muscles	Osteomyelitis of the tibia or fibula
Peripheral neuritis (e.g., post-diphtheritic)	Epiphysitis of the tibia or fibula
Muscular dystrophy, especially Tooth's peroneal type (p. 79)	Rickets
Rupture of the plantaris longus muscle	Erythema nodosum
Chronic periostitis of the tibia or fibula:	Phlebitis and thrombosis of veins
(a) traumatic, (b) tuberculous, (c) syphilitic	Embolism (infective endocarditis).

4. Causes affecting the Knee-joint:—

Traumatic synovitis	Foreign body, such as a needle, pin, or thorn
Loose cartilage	Suppurative arthritis
Tuberculous knee-joint	Prepatellar bursitis
Congenital syphilis of the knee-joint	Star-fracture of patella
Rheumatic fever	Peliosis rheumatica
Still's disease (p. 472)	Hæmophilia
	Hæmophilia with hæmorrhage into the joint.

5. Causes affecting the Thigh :

Bruising
 Infantile paralysis
 Chronic periostitis of the femur : (a) traumatic, (b) tuberculous, (c) syphilitic
 Green-stick fracture of the femur
 Sarcoma of the femur
 Osteomyelitis of the femur

Epiphysitis of the femur
 Rickets
 Tuberculous disease of the bursa beneath the tendon of the gluteus maximus
 Phlebitis (thrombosis)
 Embolism (infective endocarditis).

6. Causes affecting the Hip-joint Region or Groin :—

Tuberculous disease of the hip-joint
 Traumatic synovitis of the hip-joint
 Epiphysitis of head of femur : (a) acute, (b) chronic
 Separated epiphysis of head of femur, from injury
 Congenital syphilitic disease of the hip-joint
 Dislocation of the hip : (a) congenital (*coxa vara*), (b) from injury

Inflamed glands in the groin
 Inguinal hernia
 Femoral hernia
 Retained testicle
 Psoas abscess
 Peliosis rheumatica
 Henoch's purpura
 Haemophilia

with haemorrhage into the joint.

7. Causes affecting the Pelvis or the Lower Part of the Spine :—

Injury
 Tuberculous caries

Sacro-iliac joint disease
 Acute osteomyelitis of the ilium.

Many of the above conditions need no detailed discussion : the diagnosis may be clear from the locality of the pain, the transient or persistent nature of the limp, or the existence of visible inflammation or swelling. Doubts are likely to exist in connection with the earlier stages of tuberculous disease of the digits, tarsus, ankle, or knee, and it may not be until persistence of the painful limping points to the lesion being other than simple that the real nature of the case forces itself upon one's mind. Examination with the X rays may help materially, and the same applies to other affections of the bones—periostitis, green-stick fracture, new growth. Treatment by rest will be enjoined pending diagnosis : the latter may not become clear until the case has been watched and the course of the symptoms followed. Growing pains may be relieved by salicylates : they are nearly always to be regarded as acute rheumatic, and a careful watch will be kept upon the heart lest the child be allowed to be up and about with acute endocarditis after the pains have been relieved by the salicylates.

It is in connection with the hip region that the diagnosis of the cause of the pain that leads to limping is so difficult, especially when the child complains that it is the knee which hurts, though the disease is really in the hip—an example of referred pain due to the obturator nerve which supplies the hip sending a small geniculate branch to the knee. The hip-joint is embedded so deeply in muscles that it is often difficult to make out any local swelling, such as is generally distinctive of similar pulpy disease of the knee or ankle. Even X-ray examination may fail to give clear evidence of disease when the latter is in an early stage, though skilled radiologists may detect rarefaction of the trabeculae in the head of the femur on comparison of the two sides long before there is bony destruction to cause any difference in contour. When, however, the patient complains of persistent pain in the hip-joint region, less severe some days than others perhaps, yet not disappearing as the days go by : when this pain makes him walk with a limp, or wake with a start and cry out at night : if there are no pains elsewhere in the body, and if there is some irregular though possibly only slight pyrexia—tuberculous disease of the hip-joint would be suspected even if the child looked well, and still more so if he looked delicate and had not a robust appetite. The suspicion would be rendered almost a certainty if, on getting the child to stand stripped, in a good light, one found definite asymmetry of the buttocks, that of the painful side being flabbier or obviously smaller than the other, the natal fold beneath it running at the same time obliquely downwards and outwards, instead of nearly horizontally, as it should normally (*Fig. 377*). It is always the muscles immediately above an affected joint that waste first—the thigh muscles when the knee-joint is diseased, the glutei in the case of the hip-joint, and so on. It may also be noticed that the patient holds the whole limb on the painful side in an abnormal attitude—slightly abducted and outwardly rotated in the very earliest stages, so that there is apparent (but not actual) lengthening :

adducted and inwardly rotated in later cases, with apparent shortening. Mensuration is of little assistance in arriving at a diagnosis, because it is only at a much later stage, after considerable bony destruction has taken place, that there is real shortening, and the diagnosis will have been made long before this has occurred. On attempting to move the

Fig. 377. A case of tuberculous left hip, showing the stance, and the obliquity of the left natal fold. (Cp. Dr. Haworth.)

various joints of the legs when the patient is lying flat upon his back, those of the sound limb will show no limitation of movement; on the affected side the child will allow one to move the ankle and the knee freely if care is taken not to jar the hip, but when one tries to move the hip itself muscular contractions will resist attempts at passive flexion, extension, or rotation, or the child will cry out so that one desists from trying. If one flexes both thighs slightly on the trunk, so as to allow the spine and pelvis to lie flat along a firm mattress, one finds that the sound limb can be extended until it also lies flat along the bed without altering the position of the pelvis or spine; but if one now presses the affected limb gently down to straighten it similarly on the bed, a hand held beneath the child's lumbar vertebrae detects the fact that as the thigh of the affected side gets straighter the lumbar vertebrae begin to arch: this is owing to muscular rigidity preventing free play at the acetabulum, so that instead of the head of the femur rotating as it should, without moving the pelvis, the pelvis moves with the thigh, and arching of the back results. If attention is paid to all these points it is generally possible to detect tuberculous hip-joint disease at a comparatively early date, though in some cases one may fear it without being able to diagnose or exclude it definitely.

Sacro-iliac joint disease may simulate hip-joint disease at first sight, but on careful examination it will be found that all movements at the hip-joint can be made painlessly if the sacro-iliac joint is not jarred: whereas the least jarring to the sides of the pelvis may be acutely painful. It is generally possible to locate both pain and tenderness clearly to the sacro-iliac joint region posteriorly, and thus arrive at the diagnosis.

Psoas abscess secondary to tuberculous caries of the spine may also simulate hip-joint disease closely, for owing to the extension of the caseous abscess in the psoas muscle downwards over the front of the hip-joint, in the direction of the lesser trochanter of the femur, movements at the hip-joint may be very painful—especially those of extension.

The patient is apt to keep the thigh flexed, and inwardly or outwardly rotated according to the direction in which the psoas abscess is burrowing. One would look for fullness of the deeper structures of the groin, or a definite swelling here: actual fluctuation obtainable from above to below Poupart's ligament is to be expected theoretically, but in practice it is very seldom obtainable. The main thing to look for in verifying the diagnosis is evidence of disease of the dorsal or lumbar vertebrae. If there is Pott's angular curvature of the spine the diagnosis is obvious: often, however, the disease is confined to the anterior aspects of the bodies of the vertebrae, and no bony deformity is visible in the back: one would then look specially for rigidity of the back, local pain or tenderness on gentle percussion of successive spines, or deficient mobility of the dorsolumbar region of the vertebral column when the patient attempts to bend forward or turns from side to side. The X rays are sometimes valuable in detecting the disease (Figs. 480-482, pp. 628, 629); but on the other hand, absence of X-ray evidence of caries does not exclude it.

Rickets sometimes gives rise to considerable difficulty on account of the ill-defined but often severe pains in the bones the patient suffers. The child is generally quite young—two or three years old—when these rickety pains are worst, and therefore cannot give a personal account of where they are. The bones may be variously deformed, the patient may be unable to walk properly, and one may have grave doubts as to whether there is not tuberculous disease of the spine, sacro-iliac joint, hip-joint, knee, or ankle, as well as

rickets. Repeated examinations will be made, and yet the doubts may remain. One would, however, adopt treatment by recumbent rest and good hygiene in matters of food, air, and cleanliness in either case, and it is better to prolong the period of rest lest there is tuberculous mischief, than to curtail it on the presumption that the lesion is rickets only.

When pain causing limping in a child is confined to a single joint, such as the hip or knee, it is a safe rule to say that it is never rheumatic: neglect of this rule has led to the ruin of many a joint.

Long though the list above is, the remaining conditions given in it do not call for detailed discussion. They will be diagnosed from other symptoms presented by the case besides limping.

Herbert French.

LINEÆ ALBICANTES, sometimes termed linear, or striae, atrophicæ, consist of areas of skin many times longer than broad, shiny, and white, produced by atrophy of portions of the corium, and especially of the elastic tissue.

There is no disease that really resembles them, and indeed no other condition of the skin with which they can be confounded. Macular atrophy, morphea, and leucoderma are possible exceptions: but the patches of these affections are not linear, do not shine, and do not show those small cross-wrinkles of epidermis at right angles to the axis of a linea so characteristic of lineæ albicantes: these wrinkles can be smoothed away by stretching the skin in a direction parallel to the linea, but they return at once on relaxing the tension.

The usual meaning of these linear is that the skin has been unduly stretched over some fairly long period of time: but they give not the slightest indication as to the cause of the stretching: this caution is very necessary, because when these linear are found on a woman's abdomen or breasts, it is commonly assumed that they constitute evidence of a past pregnancy: it is perfectly true that this is the commonest origin: but any other cause of swelling, such as tumour, ascites, and even fat and œdema, etc., will produce them by stretching the skin.

They are also apt to appear over the shoulders or in front of the knees, or on the flanks, thighs, or buttocks, as the result of certain postures adopted by the patient when lying in bed. In abdominal conditions, such as typhoid fever, the knees are commonly affected from being maintained in a flexed position, and transverse striae are produced above the patellæ. In pleural effusion they occur in the postero-lateral portion of the lower part of the thorax on the same side, whereas in unilateral pulmonary tuberculosis they are found on the opposite side, owing to the patient's lying on the unaffected part. In the semi-reclining position the skin is stretched in the lower dorsal region, and striae occur in this part of the body. They generally begin in young adults when the skin is easily distensible, and are often of a purple or livid colour at first, becoming paler in course of time.

Ernest Dore.

LIPS, AFFECTIONS OF THE RED PART OF THE.—The simplest affection to which the vermillion of the lips is liable is that known as 'chapping', a condition frequently due to exposure to keen winds, and sometimes aggravated by the habit of 'picking'. In some cases the fissuring is sufficiently deep to cause appreciable pain and great disfigurement.

The vermillion of the lips may be involved also in a number of cutaneous diseases, among them *lupus vulgaris*, *lupus erythematosus*, *lichen planus*, *herpes febrilis* and *zoster*, *tinca circinata*, *urticaria*, *psoriasis*, and some forms of *syphilis*. The lesions of the epithelium of the lips, as of mucous membranes in general, are seldom characteristic enough to warrant a confident diagnosis: in none of the above affections is the red of the lips alone affected, and guidance as to the diagnosis will be found in the more distinctive lesions of the skin.

Ordinary *eczema* is sometimes limited to the lips and immediately adjacent parts. Associated with a slightly seborrhæic condition of the scalp, there is sometimes a persistent and repeated exfoliation of the vermillion of the lips (*cheilitis exfoliativa*). Similar conditions may probably be set up by the habit of biting the lips and tearing off the skin. The subjects of *cheilitis exfoliativa* are usually neurotic. In *cheilitis glandularis* there may be neither seborrhœa nor neurosis: the chronic inflammation of the lower lip, with

swelling of the mucous glands, appears to originate in catarrh of the mouth and pharynx. It is chiefly the vermillion that is affected, but the inflammation spreads to the inside of the lip, and sometimes also to the neighbouring skin, which presents an erythematous aspect. The conditions here described are all rare, and are not likely to be confused with more ordinary affections of the labial epithelium.

In *syphilis* the red of the lips is sometimes the seat of the primary sore (see *Fig. 94*, p. 94), and in the secondary stage condylomata may occur in this situation. The chancre

may be flattish and covered with a false membrane, or it may present itself as a crateriform infiltrated ulcer.

In *epithelioma* (*Fig. 378*) the lip—usually the lower one—is frequently the point of attack, the growth beginning as a slight abrasion, crack, or papule, and running the usual course. (See *TUMOURS OF THE SKIN*, p. 886.)

Fordyce's disease attacks the red of the lips and the oral mucous membrane, the lesions consisting of small whitish or yellowish milium-like bodies, which may be discrete or coalescent, profuse or scanty. Inside the mouth the milium-like bodies are whiter than those on the lip, and are also more projecting. If subjective symptoms are present they take the form of slight burning and itching, with a feeling of stiffness. The signs can hardly be

Fig. 378.—Carcinoma of the lower lip, showing the wall-like edge of the ulcer. (By permission from *Becker's 'Die Chronischen Kopfs'*, Julius Springer, Berlin.)

confounded with those of any other affection. When the lesions are very abundant, they may simulate a solid patch; but if the tissues are stretched, the milium-like bodies can be distinguished.

Perlèche is a contagious affection almost peculiar to children, and due probably to streptococci. It usually starts at both angles of the lips as a whitening and maceration of the epithelium, which is easily detached; it extends along the epithelium towards the middle line, involving also the surrounding skin and the mucosa of the inside of the lips. There are usually some hyperæmia and inflammation, and the feeling of heat and discomfort prompts the child constantly to lick its lips—hence *perlèche*. The affection often appears in association with impetigo contagiosa, or impetiginous stomatitis, or vesicular erythema. In some cases it can only be discriminated from the mucous patches of syphilis by the absence of other secondary signs. From herpes it can be diagnosed by its symmetry and by the absence of well-marked vesicles.

Ernest Dore.

LIPURIA. (See *CHYLURIA*, p. 140.)

LIVER DULLNESS, DEFICIENT.—The most common cause for diminution of the hepatic dullness is emphysema. The chest is barrel-shaped, the lower ribs are everted, and the diminution of the dullness is at its upper part. The dullness is diminished from above downwards in cases of *tight lacing*, which forces the liver down, and in cases of *hepatoptosis*, but in these two instances the hepatic dullness descends lower than is normal, so that the total liver dullness is often natural. The hepatic dullness is diminished very considerably and rapidly in *acute yellow atrophy*; the signs of this disease are so striking that the diagnosis is not as a rule difficult (p. 416). It slowly diminishes when the liver shrinks in the terminal stage of *cirrhosis*. It is often said that in *perforative peritonitis* the presence of free gas in the peritoneal cavity leads to a diminution of the hepatic dullness; this is undoubtedly true sometimes, but the sign is so often absent that, considering there are

other causes of diminution of hepatic dullness, it is unwise to lay much stress on its presence or absence in coming to a diagnosis of perforative peritonitis. Considerable *gaseous distention of the bowels* will also cause diminution of the hepatic dullness, and so will a *pneumothorax* on the right side.

W. Hale White.

LIVER, ENLARGEMENTS OF THE. In adults the liver is about $\frac{1}{36}$, but at birth it is $\frac{1}{24}$ to $\frac{1}{18}$, of the weight of the whole body; therefore in infants and young children it is relatively larger than in adults. Unless this is remembered, the liver may in such patients be thought enlarged when really it is of normal size. On deep inspiration, in thin people whose abdominal muscles are lax, the lower edge of the normal liver can, in the supine position, be felt to descend to touch the fingers if they are thrust up under the ribs outside the right rectus. In the upright position it may descend half an inch lower than this. In the epigastric angle a small portion of the anterior surface of the left lobe is in contact with the anterior abdominal wall, but often this cannot be felt owing to rigidity of the recti abdominales muscles.

The hepatic dullness to the left of the sternum cannot be distinguished from that due to the heart; on the right, it begins at the middle of the ensiform process of the sternum, in the right nipple line it reaches the upper part of the fifth intercostal space, in the mid-axillary line the seventh, in the line of the angle of the scapula the ninth. In health the edge of the liver is firm and uniform, and the surface feels smooth. If the liver is transposed, the right lobe is small and the left large. Occasionally either lobe is dwarfed by disease, e.g., alcohol or syphilis. A tongue-like projection of the right lobe may protrude from its lower right-hand part; this projection, known as *Riedel's lobe*, is commoner in women than in men, and it is often attributed to the effects of tight-lacing or the wearing of a tight belt round the waist; but as it may be found in quite young children it must be regarded as sometimes an anatomical abnormality. A Riedel's lobe may give rise to great difficulties of diagnosis; if the connection between it and the liver is only peritoneum it may be mistaken for a floating kidney, especially as in such a case there may be a band of resonance between it and the liver; or the lobe may be confused with a large gall-bladder, or any tumour that may be found on the right side of the abdomen. When palpating the abdomen it is often difficult to tell the right-hand lower part of the liver from the kidney even when there is no projection which can be called a Riedel's lobe.

Many conditions quite unconnected with the liver cause an apparent alteration in its size. Thus, a general weakness of the tissues may lead to its dropping downwards in the erect posture from laxness of its supports, which are chiefly its ligaments, and to a less extent the abdominal walls. I have known this occur in wasting diseases, the fact that the liver was not enlarged having been evident on post-mortem examination; indeed, in such a case I have known the dropped liver to be regarded as enlarged from cancer, which was believed to be the cause of the wasting, when in reality the patient was wasted because he had diabetes. Again, if the liver is somewhat enlarged from disease, its extra weight may cause it to drop, and hence it appears larger than it really is. Thus it is not uncommon for a nutmeg liver to appear during life larger than it is unless percussion shows the upper line of hepatic dullness to have descended.

Alterations in the chest may lead to depression of the liver, which may then be thought erroneously to be enlarged. The right lobe may be depressed into the right loin by compression of the chest due to tight lacing, this being often associated with a movable right kidney. Deformities of the chest due to rickets or curvature of the spine may lead to great depression of the liver. It may be depressed by large collections of fluid in the right side of the chest, but they must be quite large, for the fluid will more easily compress the lungs and push the heart to the left than depress the diaphragm. It may also be depressed by a right-sided pneumothorax. If in diaphragmatic pleurisy the diaphragm is not working, and is in a more or less constant position of inspiration, the liver is also constantly in this position, and hence seems to be a little depressed. Extreme pericardial effusion is said to depress the liver, but this must be very rare. It is often stated that a subdiaphragmatic abscess will depress the liver considerably; but this also is very rare, for the numerous adhesions in connection with such an abscess generally prevent depression of the liver.

Tight lacing may cause a deep furrow on the liver palpable during life. I have known

so deep a furrow caused by a man's belt that the part of the liver below the furrow felt almost separated from the rest of the organ ; in such a case there may be a false impression of enlargement. The effect of corsets or other artificial pressure is often such as to give an incorrect impression of enlargement, because the organ is pressed down ; most commonly the liver is forced down, flattened, and elongated from above downwards. Such a pressure often leads to a transverse depression across the right-hand lower part of the right lobe, so that a more or less detached portion of it lies in the position of a Riedel's lobe.

It is quite rare for enlargement of the liver to lead to any upward extension of the hepatic dullness. This is what might be expected, for the mere weight of the enlarged liver will lead to its falling ; the resistance of the intestines and abdominal walls is much less than is that of the diaphragm. Raising of the upper limit of hepatic dullness is best observed when some local disease of the liver directly implicates the diaphragm ; thus, a tropical abscess of the liver growing from its upper surface will soften the diaphragm and extend upwards ; a hydatid cyst will do the same. So, when there is an extension upwards of the upper hepatic dullness, it is a local extension forming a dome-shaped addition to the hepatic dullness. Very large collections of ascitic fluid or very large abdominal tumours may push the liver up, but this is excessively rare, for such conditions will more readily compress the intestines and bulge the abdominal walls. A subdiaphragmatic abscess, by its extension of dullness up into the chest, may appear to extend the liver dullness upwards.

There are three moderately common tumours in the abdomen which may give a false impression of increase in the size of the liver. They are : *A stomach affected with malignant disease*, especially when the growth infiltrates much of the greater curvature ; *malignant disease of or impaction of faeces in the transverse colon* ; and the great omentum thickened and puckered up towards the transverse colon by some form of *chronic peritonitis*, especially *tuberculous*. Any of these tumours may move up and down with respiration, for they are all directly or indirectly attached to the liver ; but the movement is not usually so extensive as that of the liver should be, and a band of resonance may sometimes be detected between the liver and the tumour, or the edge of the liver may be felt above it. Enlargements of the pylorus, and thickening in connection with a gastric or duodenal ulcer, may all be difficult to distinguish from an enlarged gall-bladder. The hepatic dullness may be altered by gas, and it may be almost obliterated by the descent of an emphysematous lung ; slight lowering of the upper margin of the hepatic dullness from this cause is quite common. In emphysema, too, the lower ribs stand so far forward that it may be impossible to feel the lower edge of the liver. When, as in perforative peritonitis, there is free gas in the peritoneal cavity, the gas getting in front of the liver may diminish the hepatic dullness, but this sign is so often absent that its absence must not be used as an argument against the existence of perforative peritonitis. On the other hand, partial obliteration of the hepatic dullness may be due to the fact that some of the intestine is between the liver and the anterior abdominal wall, or that there is much gaseous distention of the colon and the liver. A large collection of ascitic fluid often renders it difficult to estimate the size of the liver.

Hepatoptosis, and *wandering liver*, are terms applied to a liver which, being unduly displaceable, leaves its normal position. It is rare, but must be borne in mind, for, if not, a liver which is only displaced may erroneously be thought to be enlarged. Extreme degrees are met with in cases of general visceroptosis. It is commoner in women than men, and mostly after forty. The abdominal walls are usually pendulous, and as the abdominal muscles are powerful agents for keeping the abdominal viscera in place, this weakness, combined with a laxity of the hepatic ligaments, is probably the cause of the hepatoptosis. Tight lacing leads to weakness of the abdominal muscles, as well as pressing the liver down. It is flattened, often extending to the umbilicus, with its greatest prominence near its lower part and on the right. It may form a protrusion of the abdominal walls ; it is easily palpable, moves up and down with respiration, and can usually be pushed back into its normal position when the patient lies down ; indeed, when the patient is in the supine position it sometimes goes back of its own accord, only to fall again when she stands up. It is movable laterally, and can be rotated with the hands about a horizontal axis. There is considerable diminution in, or even absence of, the hepatic dullness in the chest ; in an extreme case the hand may be passed up between the liver and the ribs, and at the upper right-hand

part of the abdomen there is a depression between the liver and the ribs. There may be no symptoms, but the patient usually complains of a dragging pain and a heaviness in the hepatic region. These are much worse in the erect posture, so that she may have always to lie down. Often, sudden attacks of pain occur in the right of the abdomen; these may be due to gall-stones or to a movable kidney, both often present with hepatoposis, or to kinking of the bile-duct, which may lead to jaundice. The patients are usually neurotic, dyspeptic valetudinarians. As the abdominal muscles are weak, the blood stagnates in the abdominal vessels in the erect posture; hence faintness, palpitation, exhaustion, and dyspnoea on exertion are common, these symptoms passing away when the patient lies down.

We shall now consider each of the pathological enlargements of the liver, and indicate the chief points to be utilized in the diagnosis of each.

Venous Congestion of the Liver, or Nutmeg Liver. There must be heart disease, usually of the mitral valve, or perhaps incompetence of it secondary to severe aortic disease, or disease of the valves on the right side, or severe disease of the myocardium, or chronic pulmonary disease, usually emphysema and bronchitis, or arteriosclerosis or chronic nephritis with high blood-pressure and secondary heart failure. The enlargement of the liver is uniform, its edge is firm, its surface smooth. It may reach to the umbilicus or lower, and as the abdominal muscles are often weak in these cases, especially in women, and the liver is very heavy from the extra amount of blood in it, the organ is often a little dropped. Pain and tenderness over it are common when the heart failure is acute or recent, causing rapid stretching of the hepatic capsule, but when a nutmeg liver has existed for weeks it is no longer painful or tender. In severe cases there is often slight jaundice. Dyspeptic symptoms are frequent. Ascites may be present; if so, it is generally associated with oedema of the feet and legs as well.

In a severe degree of nutmeg liver the organ may pulsate. If so, the tricuspid orifice must be incompetent and the right ventricle must be beating strongly, or else there must be tricuspid stenosis as well as mitral stenosis, the right auricle contracting forcibly and sending a strong pulse-wave back into the inferior vena cava and hepatic veins to reach the liver, making the whole organ expand synchronously with each contraction of the right side of the heart. Such incompetence of the tricuspid orifice is nearly always secondary to mitral disease, and tricuspid stenosis is almost never present without mitral stenosis. Polygraph tracings from the liver may be required in establishing the diagnosis. Great care must be taken not to mistake a thrust downwards of the liver by the contraction of a hypertrophied heart, or the thrust forwards by a pulsating aorta, for hepatic pulsation. The distinguishing feature of this is that, when one hand is placed on the front and the other on the back of the abdomen over the enlarged, congested liver, the two hands can be felt to be separated by the expansile pulsation. This is not the case when the pulsation is transmitted. Pulsation of the veins of the neck is generally pronounced in cases in which the liver can be felt to pulsate.

General Congestion of the Liver.—This is frequently said to be present in those who suffer from dyspepsia, but if this be so it does not give rise to a demonstrable enlargement. When, however, a European lives for many years in a tropical country he is liable to suffer from attacks of congestion of the liver, and these, when frequently repeated, lead to an enlargement called *tropical liver*. The organ is uniformly enlarged, smooth, somewhat hard, with a uniform edge: pain and tenderness in it and over it are not prominent features, though the liver may feel uncomfortable to the patient. The condition is often associated with indigestion, errors of diet especially the taking of too much alcohol—and attacks of pyrexia. When these are present the liver becomes tender, painful, and more enlarged, and I have known such a condition mistaken for hepatic abscess; indeed, it may be very difficult to decide between tropical liver and tropical abscess without watching the patient for some time. Both conditions may have a common pathology, be but variations in degree of the same thing. The sufferer complains of a sensation of weight in the hepatic region; he is constipated, and the urine is full of lithates. In an extreme and chronic case the organ may extend four inches below the ribs: the patient is depressed, irritable, and of a sallow complexion. The spleen may be enlarged.

Obstruction to the Common Bile-duct, whatever the cause, is often associated with uniform enlargement of the liver owing to the fact that the bile is dammed back into it

and so swells it up : even simple catarrh may do this : jaundice will always be present at the same time, and the differential diagnosis is discussed under that heading (see JAUNDICE, p. 405).

Suppuration within the Liver. Multiple pyæmic abscesses within the liver, which constitute part of the condition known as *portal pyæmia*, generally do not cause as much enlargement of the liver as one might expect, nor, as a rule, do multiple abscesses connected with the bile-ducts—*suppurative cholangitis*—unless there is sufficient obstruction to cause jaundice at the same time. Rigors, pyrexia, and tenderness of the liver are prominent features of most such cases. Enlargement of the liver is more often present with a *large single abscess*. There is usually a history of dysentery, for amebic dysentery is by far the commonest cause of a large single abscess : it usually occurs in the tropics, and is then commonly called a tropical abscess. Very rarely it is secondary to other specific fevers, it may be due to suppuration round a gall-stone, or may spread from some neighbouring suppuration, e.g., a perinephritic abscess : or, again, it may be caused by suppuration of a hydatid or of an hepatic hæmatoma caused by injury. The presence of any of these causes may help the diagnosis : but sometimes, even when the abscess is due to the dysenteric amœba, it may be difficult to obtain a history of dysentery : indeed, the dysenteric ulcers of the intestine may have healed years before the symptoms of hepatic abscess show themselves. Very rarely it appears to follow intestinal ulceration which, as far as we know, is not dysenteric : this is so in some of the examples of single large abscesses in which the patient has never left this country. Sometimes a single large hepatic abscess is found in the tropics when the most careful search fails to find any amœbæ in the pus of the abscess, or to obtain any history of dysentery, or only a history of bacillary dysentery. Tropical abscess is most common in men between the ages of twenty-five and forty-five. It is much commoner in Europeans than natives. Eighty per cent are in the right lobe, usually in its upper part. The colour of the pus depends upon the amount of broken-down hepatic tissue present : if there is much, it is the colour of anchovy paste : if there is none, it is yellow : but the anchovy-paste-like pus is characteristic. Amœbæ may be found in it, or more often in the granulation tissue forming the wall of the abscess. Bacteria may be present, but if the abscess has existed some time the pus is often sterile. The symptoms and physical signs to which attention must be directed are as follow :

General. The most important is pyrexia : often this is the initial symptom. At first the rise of temperature is slight and irregular : gradually it becomes hectic, with a wide daily excursion, say from 99° F. in the morning to 103° F. or 104° F. in the evening. Often the patient is thought to have malaria, but an examination of the blood will show that no malarial organisms are present, and generally there is leucocytosis, whereas in malaria the tendency is towards leucopenia. There are sometimes considerable intermissions during which the temperature is normal for weeks or months, and then there is a week or so of pyrexia. When such a case occurs in this country mistakes in diagnosis are very likely. I

of a man afflicted with tropical abscess whose attacks of pyrexia were separated by long intervals of normal temperature that he was thought by many physicians to have current influenza, and this although it was well known that he had been in the tropics. Rigors are striking and severe, and in cases of doubtful diagnosis are very suggestive of hepatic abscess, though they also make this disease resemble malaria. In mild cases the rigor is reduced to a mere feeling of chilliness. Often there are profuse sweats. The pulse is rapid in proportion to the temperature. Jaundice may be present, but generally is not. In bad cases the patient is excessively ill and weak, anæmic, and wasted to a mere skeleton. In this country we see such cases on their arrival from India, the disease having made rapid progress on board ship. On the other hand, if there are long intervals of apyrexia the patient hardly suffers in his general health : in such cases the abscess usually has thick walls. The blood may show a great increase of polymorphonuclear cells, but this leucocytosis is often absent, especially if the pus is sterile or the abscess has thick walls. During the fever the patient has a dry tongue, anorexia, and is thirsty : the urine is scanty and high-coloured, and may contain albumin.

Local.—The abscess is most often at the upper part of the right lobe, grows upwards between the layers of the coronary ligament, and thus forms an extraperitoneal subphrenic abscess which softens the diaphragm and pushes it up, giving a dome-shaped area of dullness

varying in size from one to several inches across, added to the top of the normal line of the hepatic dullness, and best seen by mapping out the dullness with a blue pencil ; or visible as an upward bulge of the right cupola of the diaphragm in a skiagram (*Fig. 379*). It is usually posterior to the mid-axillary line. Sometimes the abscess is in such a place that a rounded swelling may be felt, or even seen, on the liver when the patient draws a deep breath. The measurement round the lower part of the chest may be longer on the affected side, the intercostal spaces may be obliterated, and if the abscess be very large, the lower ribs may bulge. Not uncommonly the abscess is of such size and position that the greatest care is necessary before it can be detected. The whole of the hepatic area should be pressed carefully by one finger, for local tenderness is often a great aid in the diagnosis. If the abscess presents in the abdomen the rectus muscle over it may be rigid. Pain is very variable ; it may be absent, it may be severe : often coughing, drawing a deep breath, or shaking the patient, will cause pain. In about one-sixth of the cases there is pain in the right shoulder : if the abscess is in the left lobe, there may be pain in the left shoulder. If the abscess comes close to the skin there may be oedema and redness over it, and, in excessively rare cases, fluctuation. Often the liver is enlarged generally as well as locally. If the abscess is large, it may be seen with the X rays, for pus casts a very dark shadow. If it implicates the diaphragm, infection may spread through it and cause bronchitis, pleurisy, empyema, pneumonia, or gangrene of the lung, but this is not nearly so common as with other subphrenic abscesses : hepatic pus may be coughed up from the lung when the abscess has ruptured into it, may be vomited when it has ruptured into the stomach, or may be passed by the bowel when it has ruptured into the intestine. I would again remind the reader that in some of the chronic cases seen in this country both the local and general signs may be so slight that great skill is necessary to detect the abscess.

Fig. 379.—Skiagram showing the way in which the right cupola of the diaphragm may be pushed upwards by a large tropical abscess of the liver. The same appearance might be produced by a large hydatid cyst in the liver, or by a non-tropical subphrenic abscess on the right side. (*Rev. Dr. C. Thorstein Holland.*)

Cirrhosis of the Liver. Nearly always in this country the patient has taken more alcohol than he should, but cirrhosis of the liver, indistinguishable from alcoholic cirrhosis, occurs in children and others who have not taken alcohol, especially in Egypt. Here we have to consider only the stage in which the liver is enlarged. It has been known to weigh 200 oz., but anything over 100 oz. is exceptional. In the early stages the liver is not altered in shape, and the surface and edge are smooth : later on, as the fibrous tissue contracts and the fat is absorbed from the cells which have undergone degeneration, the surface becomes finely uneven : this unevenness increases, the liver becomes hard and more uneven until the irregularities on it are like hobnails, and can be felt through the abdominal wall. At this stage the edge of the liver is irregular and very firm. As the irregularity increases, the diagnosis from cancer becomes more difficult, but no irregularity from cirrhosis ever exceeds the size of a small cherry, nor is it ever umbilicated, nor does it ever enlarge suddenly ; whereas a cancerous nodule may be umbilicated and may enlarge suddenly from hemorrhage into it. Usually a cirrhotic liver is not painful ; if it be, the pain is due to some local perihepatitis. Other symptoms to be looked for in cirrhosis, and also to be borne in mind when making a diagnosis, are that the spleen is often enlarged, and sometimes much so : the increased fibrous tissue in the liver constricting its small portal veins leads to engorgement of the veins of the stomach, and hence hæmatemesis, which may be accompanied by melæna, is common at some period in the case : and occasionally we see dilatation of the veins round the umbilicus. There are often symptoms of chronic gastritis and enteritis. Cirrhosis is commoner in men than women in the proportion of three to one ; the patients are usually over thirty ; there is a more frequent association of alcoholic excess in the lower classes than among those who are socially above them. Dyspepsia and

morning sickness are common ; there are much impairment of strength, wasting, a sallow, pigmented facies, dilated venules on the cheek, red nose, a furred tongue which is often tremulous, and a dry, harsh skin. The pulse becomes weaker as the disease progresses, and the end is usually by cardiac failure. In about one-third of the cases that are ill enough to come into hospital, the temperature is raised a little every evening (see *Fig. 66*, p. 47). Jaundice is or has been present in about one-third of the cases ; it rarely if ever becomes as deep as that seen in cancer of the liver. Ascites occurs in 50 per cent of all cases of cirrhosis, but generally in the latest stages only ; if it is abundant the enlarged liver can be felt only by dipping, which means pressing the hand down suddenly on the liver, and so, by dispersing the fluid which is over it, coming down on it. Tympanites is not uncommon in severe cases of cirrhosis, and it too may make it difficult to feel the liver. The urine is usually scanty, of high specific gravity, very acid, high-coloured, and full of urates ; it generally contains urobilin and sometimes bile. Naturally sufferers from cirrhosis may have delirium tremens, but apart from this, cirrhosis towards the end is often accompanied by nervous symptoms, especially mental obfuscation, delusions, and coma, and this may be so even in those who have not recently taken alcohol and who are not jaundiced. In severe cases the ankles swell, even when there is no disease of the heart, lungs, or kidneys, or pressure on the vena cava, to account for it. Lastly, it should be remembered that cirrhosis may exist without any symptoms ; in between a third and a half of all cases of cirrhosis found in the post-mortem room the patient has died of something else, and in many of these cases, although he has been under observation in the wards, no symptoms of cirrhosis have been observed.

The difficulties of diagnosis fall into one of two classes : the cause of ASCITES (p. 61), and the cause of enlargement of the liver. If we have made out that the liver is undoubtedly enlarged, it is often a matter of great difficulty to tell whether this is due to cancer or to cirrhosis. Sometimes cancer and cirrhosis are present in the same liver, but this is rare. Syphilis of the liver does not cause much difficulty, for it is uncommon at the bedside ; the irregularities of the liver are much larger than the hobnails of cirrhosis ; the patient who has a syphilitic liver is rarely jaundiced, and hardly ever has ascites. The symptoms of a syphilitic liver are nearly always entirely local ; syphilitic disease of the liver rarely produces general symptoms. Obstruction of the common bile-duct leads to a large smooth liver ; when this is due to a gall-stone there is usually deeper jaundice than in cirrhosis, but no ascites ; the stools are quite pallid, which is very unusual in cirrhosis, and there is commonly a history of gall-stones. There is no real difficulty of diagnosis between the enlargement of malaria and ordinary cirrhosis, for so-called malarial cirrhosis occurs only in those who have drunk to excess, and is then to be ascribed to alcohol.

Hanot's Cirrhosis often called hypertrophic biliary cirrhosis, an extremely bad name, is a very rare disease, of which the distinguishing features are : Most of the sufferers are children ; few reach the age of thirty ; it is commoner in males than females ; it lasts many years ; the liver is firm, enlarged, and smooth ; long-standing jaundice is present ; the spleen is very much enlarged. The patients are usually children of stunted growth, and therefore the liver appears very large, but the spleen is proportionately more enlarged. The liver usually remains smooth throughout, and even when towards the end of a long case it becomes a little granular, it never proceeds to anything like the irregularity of ordinary cirrhosis. Jaundice is an early and fluctuating symptom and lasts till the end, so it may be present many years ; very, very slowly it becomes darker. From time to time the patient has periods during which he feels ill and his temperature is raised ; but it is strange that in spite of their jaundice the children afflicted with this disease do not for years appear ill ; they may be seen running about enjoying life, with a clean tongue and a good appetite. Ascites is rare, and if present means that the end is near. In many cases the fingers become clubbed ; the clubbing is exactly like that seen in chronic fibrosis of the lung. As growth is stunted—for example, whereas the average height at 13 years is 4 ft. 9 in., a patient with this disease was only 4 ft. 1 in.—the size of the liver and spleen makes the abdomen very prominent. At the later stages there may be purpura and other hæmorrhages.

Splenic Anæmia.—This is a disease in which there are progressive enlargement of the spleen, secondary anæmia, leucopenia, a marked tendency to hæmorrhage, especially from the stomach, and in many cases a terminal stage of cirrhosis of the liver, jaundice, and

ascites. The disease is often called *splenomegalic cirrhosis*, and its terminal stage of cirrhosis of the liver is frequently designated *Banti's disease*. When in this terminal stage the liver is enlarged from cirrhosis it may be almost impossible to distinguish the condition from ordinary cirrhosis of the liver unless we know from the medical history of the case that the spleen has been enlarged for some time. Other points that may help are : on the average the spleen is much larger in splenic anaemia than in ordinary cirrhosis, so that an excessively large spleen is somewhat in favour of splenic anaemia ; hamatemesis is an early symptom, usually present long before the stage of cirrhosis of the liver. The disease is very slow, but the patient may die before the supervention of either ascites or jaundice ; he does not often do this in ordinary cirrhosis. Anaemia is present in both conditions, but is, on the whole, severer in splenic anaemia.

Bronzed Diabetes.—In this disorder, which is very seldom seen, the liver is enlarged, hard, and cirrhotic, exactly like that of an ordinary cirrhosis : the pigmentation of the skin, which is like the discoloration due to arsenic, the absence of jaundice, and the presence of sugar in the urine, sufficiently distinguish the disease : the diagnosis may be in doubt until a post-mortem examination is made ; the cirrhotic liver is then found to give a typical Perle's prussian-blue reaction similar to that seen in pernicious anaemia, and this is not the case in ordinary cirrhotic livers.

Syphilis of the Liver. Syphilis when it affects the liver produces gummata in it and leads to increased growth of fibrous tissue. Much of this is in the form of hard bands, traversing the liver irregularly and leaving large areas of healthy liver substance, so that, what with the presence of recent gummata, gummata that have begun to shrink, bands of fibrous tissue that have begun to contract, and pieces of normal liver, a syphilitic liver is very lumpy and irregular. It may be enlarged, and even during life this lumpiness may be felt, but the syphilitic liver does not become so large as a large cirrhotic liver, unless lardaceous disease be present : it is much more irregular, and indeed usually resembles a cancerous more than a cirrhotic liver, but it seldom produces any clinical symptoms : if detected during life the discovery is generally accidental : it occurs at a younger age than cancer : there are none of the other signs of cancer, but there may be some of syphilis, and the Wassermann reaction will be positive ; ascites and jaundice do not occur as signs of this disease unless an enlarged gland presses on the portal vein, which is so rarely the case as to be negligible ; and the liver is at most a little enlarged, never huge as in cancer.

In children, congenital syphilis may produce in the liver precisely the same effects as the acquired disease does in adults, but in addition it may also cause a generalized smooth, hard enlargement due to pericellular cirrhosis. The hardness of the smooth big liver in a child suggests the diagnosis, and the Wassermann reaction in the blood clinches it. Lardaceous disease may be due to syphilis : it will be discussed presently.

Universal Chronic Perihepatitis may make the liver appear large, for the peritoneal coating of the whole organ is much thickened ; but as the liver itself is of normal size the apparent increase is not great, rarely exceeding an extra finger's breadth below the ribs. Such of the liver as can be felt is smooth ; the edge is uniform and thick. Usually, however, no apparent enlargement can be detected in universal chronic perihepatitis, and often the organ and its thickened capsule weigh the same as a normal liver. There are no hepatic symptoms, e.g., jaundice, and the universal perihepatitis is only part of a general chronic peritonitis, symptoms of which, e.g., ascites and thickening of other parts of the peritoneum, may be detected on palpation.

Secondary Cancer of the Liver.—This is the commonest tumour of the liver. Generally there will be symptoms of the primary malignant disease, which in about 90 per cent of the cases is in the periphery of the portal area, but not infrequently none are present, and the patient does not know that he has anything serious the matter with him until he has symptoms of hepatic carcinoma. On the other hand, in about half the cases of hepatic carcinoma no symptoms of it are present, and it is not known to exist until a post-mortem examination is performed, for the primary disease kills while the hepatic disease is still in its early stages. Seventy-five per cent of all the patients are between 40 and 70 years old, and hepatic carcinoma is all but unknown under the age of 20. If the disease gives rise to clinical symptoms the liver can usually be made out to be enlarged both by percussion and palpation. There is no other disease in which such a huge liver may be found. I have known a cancerous liver to weigh 19 lb., and I have read of one which weighed 33½ lb. ;

weights of 6 or 7 lb. are quite common. In rare cases the increase in the weight of the liver may be so great that the patient actually gains a little weight in spite of the general wasting caused by the cancer. The organ may be felt well below the ribs, even far below the umbilicus. Often it is so big that it can be seen to go up and down with each breath. Upward increase of the hepatic dullness is rare, and when present, slight. The edge of the enlarged organ can be felt to move up and down with respiration, unless it is fixed by adhesions, which is unusual. The edge is hard, and often irregular; when the secondary nodules are numerous the whole organ feels uneven, knobby, and hard, and sometimes the lumps on it feel umbilicated; this is absolutely diagnostic of cancer. If much softening has occurred a faint sense of fluctuation may be detected; in a few instances local peritonitis causes a rub. Sometimes the nodules can be appreciated by the hand only when the patient takes a deep breath, for then those under the ribs come far enough down to be felt. Occasionally the cancer grows so fast that the liver obviously increases in size in a week: very rarely a nodule may enlarge suddenly from hemorrhage into it. Either or both these points are almost proof that the enlargement is due to carcinoma. It must not be forgotten that not all livers enlarged from malignant disease have palpable nodules, for they may be in such a situation that they cannot be felt, they may be too small to be felt, or the growth may be diffused through the whole liver. About half the patients have pain in the hepatic region, and may have it near the right shoulder and down the right arm. If the liver is very large there is a sense of dragging and fullness in the right hypochondrium. About half the patients are jaundiced. It is extremely important to remember that by far the most frequent cause of long-standing jaundice is cancer of the liver, which produces a deeper yellow of the skin than any other disease; as time goes on this yellow changes to deep olive-green. The wasting becomes extreme, the skin dry and shrivelled, the patient becomes weaker and weaker, his pulse feebler, his respiration shallow, and finally he dies comatose. The usual symptoms of JAUNDICE (p. 405) are present. ASCITES (p. 59) is rather less frequent than jaundice, and the patient generally dies before tapping is necessary, for ascites is a late symptom. The urine usually contains much bile and lithates. Rapidly growing carcinoma of the liver is often associated with an evening rise of temperature to 99° F. or 101° F. (*Fig. 323*, p. 408). I have known it to be 102° F. every evening for weeks.

The chief difficulty of diagnosis is from cirrhosis. The large cirrhotic liver is uniformly large, and the palpable nodules are small; if they feel bigger than small cherries the case cannot be one of cirrhosis, for hobnails are never bigger than this; hobnails are never umbilicated, and never increase rapidly in size; if jaundice is present and the patient has a large cirrhotic liver, the jaundice is never very deep, and remains yellow; it never becomes the dark olive-green seen in cancer. In cirrhosis we do not get clay-coloured motions or dilatation of the gall-bladder, but we often find a large spleen. Extreme wasting and hardness of the skin are more common in cancer. A moderate leucocytosis is often in both diseases in the late stages. The discovery of cancer elsewhere is of course conclusive, and the history is of great help. Syphilis of the liver has already been described sufficiently to indicate the points of difference. Cases in which, owing to non-malignant obstruction of the bile-duct, usually by a gall-stone, there are enlargement of the liver and jaundice, may give rise to difficulty of diagnosis; but these patients rarely have the extreme wasted look, with dry shrivelled skin, so frequently seen in cancer; the hepatic enlargement is uniform and never so great as it may be in cancer; the jaundice does not become green; if it disappears for a time, it means that the gall-stone has shifted; that the jaundice due to cancer should disappear is almost unknown. Rigors are common in cases of gall-stones. The age, history, and detection of growths elsewhere will be of help. As far as my experience goes, when we are in considerable doubt as to whether a patient has an impacted gall-stone or a malignant growth, exploration, if done, almost always reveals a growth. Hydatid tumours of the liver are seldom confused with cancer, for almost always these are only one or two in number, the liver is smooth and regular, and is not tender; the hydatid tumour causes neither pain, jaundice, ascites, nor general emaciation, and it may give a thrill. There is no ordinary leucocytosis, but the patient may have eosinophilia.

Primary Carcinoma of the Liver.—This is very rare; the liver has the same character as in the secondary form, but there are no symptoms of a primary growth

elsewhere. It is almost always a disease of adult life. It is usually more rapid than secondary cancer; most of the patients are dead within three months from the onset of symptoms, and therefore the jaundice has not time to become dark green. Wasting, and other general signs, including slight pyrexia, are present. During life, primary can hardly ever be diagnosed from secondary cancer of the liver, for even when the liver appears clinically to be the only organ affected, it often turns out that there has been primary disease elsewhere, giving no symptoms, and not detected till after death.

Secondary Sarcoma and Embryoma of the Liver. These do not produce enlargement enough to be detected during life—except perhaps in the case of melanotic sarcoma secondary to a tumour of the eye, when the liver may enlarge very rapidly and to an extreme degree—for the primary disease and the numerous secondary deposits elsewhere than in the liver soon kill the patient. If melanotic growth is suspected, the urine should be tested for melanin (p. 905).

Primary Sarcoma of the Liver is very rare, and during life cannot be distinguished from primary carcinoma.

Adenomata of the Liver are also very rare: they are hardly ever of sufficient size to be detected during life. They are single, and I know of an instance in which a large one was operated on under the impression that it was a hydatid.

Lymphadenomata of the Liver. New formations consisting of lymphoid tissue, generally diffused through the whole liver but sometimes occurring in nodules, may be seen in those dying from Hodgkin's disease or from lymphatic leukaemia. The nodules cannot be detected during life, but in a few cases the diffuse variety makes the liver uniformly enlarged; it is smooth, its surface and edge are firm, it is painless, not tender, never of great size, and there is no jaundice. Leukæmic cases will be detected by the blood-count (p. 32).

Angiomata. It is not uncommon to find small angiomata in the liver in the post-mortem room, but they cannot be detected during life unless they are large enough to give symptoms which result from their size, and this is very rare. Sometimes when a large tumour of the liver has been thought to be a carcinoma, and yet the patient has seemed well enough to be suitable for operation, the growth has turned out to be a cavernous angioma, and these tumours have been excised. About fifteen of such cases are on record, and the patient was usually under fifty years of age.

Fatty Liver. This is very common, but the enlargement of a fatty liver is usually not sufficient to be detected during life, sometimes because the patients are so obese that palpation of the liver is difficult. A fatty liver, if increased in size, is uniformly enlarged, has a rounded edge, feels a little softer than natural, with a smooth surface; there is neither pain nor tenderness. The causes are so numerous that often they hardly help the diagnosis. The largest fatty livers are met with in phosphorus poisoning; they then may weigh 10 or 12 lb. Severe anæmia, wasting disease, especially tubercle, and alcoholic excess, are perhaps the commonest causes. There is neither jaundice nor any other symptom that can be attributed to the disease of the liver.

Lardaceous Liver. The liver is uniformly enlarged; the increase in size may be considerable; indeed, next to cancer, lardaceous disease causes the largest livers with which we meet. A lardaceous liver has been known to weigh 14 lb. It is so smooth that even through the skin it feels strikingly so: it is firm, and the edge is sharp and hard; it causes no pain, and is not tender. The diagnosis of this disease is much facilitated by finding lardaceous disease of other organs: thus the spleen may be enlarged considerably and uniformly, there may be albuminuria from lardaceous disease of the kidneys, or diarrhœa from lardaceous disease of the intestine. Only two causes for lardaceous disease are known, viz.: long-continued suppuration, e.g., psoas abscess, bronchiectasis, chronic phthisis with cavitation, chronic hip-joint disease with sinuses, ulcerative colitis; and long-standing syphilis, even if this has not caused any suppuration. I have known it occur in a small child as a result of congenital syphilis. In a very few instances no cause for lardaceous disease can be discovered, but this is so exceptional that we should be very cautious of diagnosing lardaceous disease in the absence of syphilis or suppuration.

Tuberculosis of the Liver. It is excessively rare for a tuberculous deposit in the liver to form a mass sufficiently large to be detected clinically; indeed, so rare is it that the diagnosis could not be made before exploration unless it were known that the patient had

tuberculous disease at the periphery of the portal vein. Judging by morbid anatomy, a tuberculous tumour of the liver would, if discovered during life, be a solitary tumour of the liver. At an exploratory operation an irregular shaggy abscess cavity would be found, the pus of which would contain tubercle bacilli. There may be some uniform enlargement of the liver in a child suffering from general tuberculosis.

Actinomycosis—or, as it is sometimes called, *streptotrichosis*—of the liver could hardly be diagnosed without laparotomy unless the patient were known to have actinomycosis elsewhere. It is very rare, and has seldom been recognized in the liver until after the patient's death. If detected during life, there would be a local enlargement of the liver. The pus in it would be in an irregular cavity with shaggy walls and trabeculae, and the characteristic little sulphur-coloured granules would be seen in it with the naked eye, and the ray fungus on examination with the microscope (*Fig.* 610, p. 779).

Hydatid Disease of the Liver can hardly be recognized unless the cyst causes a discoverable tumour of the liver. This may be huge. Hydatid cysts of the liver may contain thirty pints or more. If the tumour can be felt, it is rounded, smooth, localized, and regular, and thus is distinguished by its feel from cancerous or syphilitic livers, for in these the tumours are irregular and rough, and often there are one or more in different parts of the liver. A hydatid tumour is neither tender nor painful, and thus differs from an abscess. If the tumour projects from the lower part of the liver it may resemble a gall-bladder. A large hydatid cyst of the lower part of the right lobe of the liver causes considerable intra-abdominal enlargement of that lobe; on the other hand, if, as is frequently the case, it grows upwards between the layers of the coronary ligament, it pushes up the diaphragm, forming a rounded projection which may be percussed out in the chest as an addition to the top of the normal hepatic dullness: in exceptional cases the tumour may be so huge that the dome shape of the dullness is lost, and the case is apt to be regarded as one of pleuritic effusion. If a hydatid tumour is deep in the liver, the swelling feels hard; if it comes to the surface, the tumour feels tense so tense that fluctuation is very rare. The so-called hydatid thrill perceptible in the finger lying on the tumour when it is struck by a finger of the other hand, is not often felt: it may be obtained over any tense collection of fluid, but if it be present it is of considerable diagnostic value, for other tense cysts are very unusual in the liver. Occasionally two or even three hydatid cysts are present in the same liver; each then has the characteristics of a single cyst, but the diagnosis of these cases may give much difficulty. It is excessively rare for hydatids to cause pressure symptoms: jaundice is hardly ever seen; if present, it is probably caused by rupture of the cyst into the bile-passages. A huge cyst may displace the heart. EOSINOPHILIA (p. 271), even to a considerable degree, is sometimes found when the parasitic cyst is living and active, but not when it is quiescent or obsolete. I have seen 10 per cent of eosinophils, and even 50 per cent have been recorded. A more moderate increase is sometimes seen in cancer. Usually eosinophilia is absent in hydatid disease, but when present it is a considerable help in diagnosis. It decreases rapidly after the cyst is drained. If the hydatid fluid becomes absorbed the patient may have urticaria. When the blood serum of a patient with hydatid disease is mixed with some hydatid fluid, a precipitate may be formed after about twenty hours; this reaction is not constant, but it does not occur when hydatid fluid is mixed with the serum of a patient who has not got hydatid disease. Hydatid fluid does not give an albuminous precipitate when heated, whereas the fluid of an ordinary pleuritic effusion does. Hooklets (see *Fig.* 76, p. 65) may be found in hydatid fluid, especially after it is centrifugalized. Hydatid cysts sometimes suppurate, and then they can hardly be distinguished from other forms of single solitary abscess.

Bilharziosis seems to be the cause of smooth chronic enlargement of the liver in certain Egyptian cases; the diagnosis depends on finding the *Bilharzia* ova in the urine (*Fig.* 96, p. 102).

Other cysts of the liver are very rare and very difficult to diagnose. Special textbooks dealing with the liver should be consulted about them. W. Hale White.

LYMPHATIC GLAND ENLARGEMENT.

I. GENERALIZED ENLARGEMENT.

There are certain diseases in which there is a tendency for all or nearly all the lymphatic glands in the body to be enlarged—generalized glandular enlargement, as distinct from enlargement of local groups of glands only. The distinction is not absolute, however, for in some patients suffering from a malady which usually causes general lymphatic glandular enlargement the changes may be confined to local groups instead of being as widespread as usual. It may be said, however, that if there is generalized enlargement of the lymphatic glands, the patient is probably suffering from one or other of the following diseases :—

Lymphatic leukaemia	Secondary syphilis	Generalized skin-sepsis, e.g.,
Hodgkin's disease	German measles	from extensive furunculosis
Lymphadenoma	Still's disease	or scabies.
Lymphoma	Plague	
Lymphosarcoma	Tubercle, rare type	

It is, of course, important to be quite sure that the glands are really enlarged, and not merely palpable with greater ease than usual : experience alone will decide this question. There are many conditions in which wasting affects the subcutaneous fat and not the lymphatic glands, so that the latter are felt with considerable ease, especially in the groins. General glandular enlargement usually implies affection of the cervical, axillary, and inguinal glands at the same time : those in the popliteal space or above the internal condyle of the humerus are less often affected : the various groups within the abdomen can seldom be palpated, unless perhaps in the iliac region or pelvis, whilst enlargement of the mediastinal and bronchial groups can only be surmised when there is evidence of obstruction to one or other bronchus, or when they can be demonstrated by the X rays (*Fig. 155*, p. 187).

When a case of generalized lymphatic glandular enlargement presents itself it is important to make a blood-count : the blood-changes will either indicate *lymphatic leukaemia* (see ANÆMIA, p. 33), or else, if the characteristic leucocyte counts of the latter are not found, lymphatic leukaemia will be excluded. None of the other conditions exhibit pathognomonic blood-changes, although there will very often be a considerable degree of anaemia of the chlorotic type.

Hodgkin's disease nearly always starts with much swelling of one group of glands before the rest, especially those in the neck : there is usually moderate enlargement of the spleen at the same time, and in the course of weeks or months, generalized swelling of the lymphatic glands occurs, especially those in the axilla and within the thorax, the resultant masses sometimes being of considerable size (*Fig. 380*), though the individual glands remain distinct from one another, do not tend to break down and suppurate, and do not become fixed either to the skin or to the deeper parts, as they would do if they were tuberculous or due to secondary deposits of malignant disease. The blood-changes in Hodgkin's disease are for the most part negative (see ANÆMIA, p. 49), though in blood-films the occurrence of an occasional basophil corpuscle or myelocyte may help to support the diagnosis.

Lymphadenoma differs from Hodgkin's disease so little that some authorities use the two names as though they were synonymous ; others reserve the term lymphadenoma for those cases in which splenic enlargement is not apparent, whilst the affection of the

Fig. 380. Hodgkin's disease. The lymphatic glands in the left side of the neck are very large ; there is considerable overgrowth of the lymphatic glands in the right axilla, particularly along the outer border of the pectoralis major muscle ; the glands in the left axilla are also enlarged, but to a less extent ; even the left epitrochlear gland is visibly enlarged.

lymphatic glands is pronounced and general. *Lymphoma* is a term that has sometimes been used in the same sense, though it is sometimes employed for lymphadenomatous cases in which a single mass of gland is alone involved—those in one axilla, for example, or those in one side of the neck—when others are not as yet affected.

Where *lymphosarcoma* ends and Hodgkin's disease, lymphadenoma, or lymphoma begins, it is difficult to say. If there is generalized enlargement of the lymphatic glands without much affection of the spleen, without any pathognomonic blood-changes, and with a rapidly fatal ending, the condition is spoken of as lymphosarcoma, but it might equally well be termed acute lymphadenoma. Lymphosarcoma is particularly prone to affect the mediastinal or bronchial glands, and a fair percentage of mediastinal new growths is due to lymphosarcoma of the mediastinal glands, the diagnosis often depending on X-ray examination of the thorax.

Syphilitic glands seldom reach any great size, only swelling, roughly speaking, to two or three times the normal: the first to be involved are those in the neighbourhood of the chancre, and therefore most often those in the groin, spreading later to all the glands in the body, including those in the occipital region, which are not as a rule affected except by syphilis, pediculosis capitis with sores, impetigo capitis, suppurating ringworm (kerion), lymphatic leukaemia, and German measles. Syphilitic glands are almond-shaped and firm, painless, or at most slightly tender, and they do not become adherent to the skin or to

the deeper parts. They may remain palpable for months after the other signs of secondary syphilis have disappeared. The difficulty in their diagnosis does not arise when chancre or roseola is present: but later their nature may not be obvious unless there is a clear history of syphilis or Wassermann's serum test is positive.

German measles causes generalized enlargement of the lymphatic glands very similar to that of secondary syphilis, but the diagnosis is generally obvious from the nature of the skin eruption. The occurrence of enlarged occipital and other glands associated with a measles-like rash serves to distinguish German measles from ordinary measles, and also from scarlet fever and other erythemata.

Still's disease attracts attention primarily on account of the affection of the joints, and the enlargement of the lymphatic glands is a symptom of secondary importance. It is an affection of children (*Fig. 381*) precisely corresponding to rheumatoid arthritis of adults: no joint in the body is exempt, and it is probable that the lymphatic glandular enlargement is secondary to absorption of micro-organisms from the infected joints.

FIG. 381.—Still's disease: subacute rheumatoid arthritis in childhood. The fingers are swollen and their ordinary outlines lost: there is typical spindle-shaped enlargement of the first interphalangeal joints.

The patient becomes anæmic, with a tendency to pigmentation, and the spleen is enlarged as well as the lymphatic glands. The disease is unmistakable. Similar lymphatic glandular enlargement occurs in the acute rheumatoid arthritis or infective synovitis or peri-arthritis of older persons, especially in that form which is characterized by spindle-shaped swelling of the first interphalangeal joints of the hands (*Fig. 332*, p. 426): but as a rule the enlargement is confined to those glands which are closest to the affected joints—epitrochlear glands, for instance, in the case of the fingers and hands, and so forth: and the glandular enlargement disappears when the malady is in its quiescent phases, although the joint deformity remains.

Plague may be associated with very acute glandular enlargement all over the body: the diagnosis depends largely on the history, and particularly upon the patient's having

been exposed to the risk of contracting plague in some infected town or port. The diagnosis may be confirmed bacteriologically.

Tuberculosis of glands is much more often local than general; occasionally, however, one meets with a case in which the inguinal and axillary as well as the cervical and internal glands are all enlarged as the result of tuberculous infection; the case then simulates lymphadenoma closely, and it may be necessary to excise one of the affected glands and examine it histologically before one can be sure of the diagnosis.

II. LOCALIZED LYMPHATIC GLANDULAR ENLARGEMENT.

In all those diseases in which enlargement of the lymphatic glands may be general it may sometimes be local, or may begin locally before it becomes general, so that in every case in which there is an affection of a local group of lymphatic glands it is important to remember the possibility of the case being due to one of the diseases already discussed under heading I.

The following additional causes, however, have also to be considered, namely:—

- Septic absorption, from sores, etc., on the skin or mucous membranes from which the lymphatics drain into the particular glands that are involved
- Tuberculous disease
- Secondary malignant disease.

Whenever there is any doubt, a blood-count should be made in order to either diagnose or exclude lymphatic leukaemia. When this can be excluded the nature of the local glandular enlargement will generally be suggested by the age of the patient, by the characters of the glands themselves, and by their locality. The particular group of glands involved may be dealt with *separatim*:

Occipital Glands. These glands seldom become enlarged as the result of leukaemia, Hodgkin's disease, lymphadenoma, German measles, syphilis, or tuberculosis, unless there is obvious enlargement of other glands at the same time. When there is enlargement of the occipital glands and no others, by far the most likely cause is septic absorption from the posterior region of the scalp, particularly from *impetigo*, *seborrhoeic dermatitis*, *suppurating ringworm (kerion)*, *suppurating teen or sebaceous cyst*, *suppurating scalp wound*, or, most likely of all, *pediculosis capitis*. Nits should always be looked for in the hair with care, and they may sometimes be found even in ladies in whom the mode of infection may be quite inexplicable; the patients generally have much irritation of the skin at the back of the neck at the same time, and it may be attributed to the rubbing of a collar or the neck of a dress. There is generally considerable anaemia, the patient looks unwell, and often has some evening pyrexia.

Pre-auricular Glands. The most common causes for enlargement of the pre-auricular glands are: *Septic infection* of the skin of the cheek, eyelid, ear, or temporal region of the scalp, or *epithelioma* of these regions. Rarer causes are *rodent ulcer*, *lupus vulgaris*, *acne*. The occurrence of enlargement of this gland in association with an ulcer which may be rodent on the one hand, and an epithelioma on the other, does not necessarily indicate the latter, for without there being secondary deposits the gland may become enlarged from absorption of bacterial products from the pus of rodent ulcer. In those very rare cases of *chancere of an eyelid* (Fig. 382) or other neighbouring part, enlargement of the pre-auricular gland may precede the generalized enlargement of the glands to which syphilis gives rise. The gland may also be the site of *melanotic sarcoma* in very rare cases, the primary growth being in the eye or a pigmented mole.

FIG. 382. Chancere of the inner canthus of the eye.
(Photograph by Major H. J. McTiernan.)

Submaxillary Glands.—The commonest cause for enlargement of these is *septic absorption* from the mouth; tonsillitis and inflammation of the fauces are responsible for most cases in which a firm gland becomes palpable just beneath and behind the angle of the jaw; generally the enlargement is greater upon one side than upon the other, and it may persist for days or even weeks after the causal inflammation in the tonsil has subsided. The glands are painful in the acute stages, and in a few cases the infection is so severe that the tissues break down, and suppurative adenitis with an abscess results. All kinds of inflammation of the throat may cause this glandular enlargement—ordinary simple tonsillitis, hospital sore throat, rheumatic tonsillitis, follicular tonsillitis, quinsy, diphtheria, scarlet fever, acute phlegmonous tonsillitis, Vincent's angina, secondary syphilis. The precise nature of the infecting organism is to be ascertained by taking swabbings from the tonsils or fauces for bacteriological cultivation. Vincent's angina produces glandular enlargement less frequently than do other severe forms of sore throat.

The enlargement may be due to tubercle even when the swollen gland is solitary, unilateral, and confined to the region of the angle of the jaw where a tonsillar inflammatory cause might seem more probable: the diagnosis is then difficult, unless the case is watched. Long persistence of the swollen gland, its gradual adherence to the skin, or the development of others farther down the neck may cause one to change an initial diagnosis of inflammatory gland to tubercle, especially if the patient is a child. Sometimes one is misled by the rapidity with which the gland swells up into thinking it is purely inflammatory when really it was already affected by tubercle and swelled rapidly as a result of superadded inflammatory infection from tonsil, mouth, or tooth. If such a gland persists it will very likely be excised, and the diagnosis made by histological examination.

Inflammatory changes in glands further forward beneath the jaw are often secondary to caries of a tooth or to some variety of stomatitis, the diagnosis being ascertained by inspection of the mouth. Less acute enlargement, going on to much greater size than is the rule with inflammatory adenitis, may result from secondary deposits of *malignant disease* in the submaxillary glands when there is squamous-celled carcinoma (epithelioma) of the tongue, lip, gum, cheek, nose, palate, fauces, tonsil, pharynx, or larynx. The diagnosis in these cases depends upon the presence of an obvious primary epithelioma: if there is any doubt as to this, a small portion of the ulcerating mass may be excised for microscopical examination. When a gummatous ulcer simulates epithelioma, the effect of iodide of potassium and mercury may point to the former, or Wassermann's serum test may be positive. A gumma of the tongue is likely to be median, an epithelioma lateral.

Cervical Glands.—Enlargement of the glands in the neck generally may be either unilateral or bilateral. If unilateral, if only a few glands are involved, and if the history is a short one, the changes are probably *inflammatory*, particularly if there has been any sore place on the skin of the neck, the buccal mucosa, or throat, or if there is evidence that the patient has been exposed recently to scarlet fever, or if there is otitis media. Acute cervical

itis with sore throat is one of the chief features of an epidemic malady, described by Land, and referred to in detail on p. 761. *Pediculosis capitis* is a common cause of enlarged cervical glands in children of the poorer classes. It is sometimes difficult, however, to decide when the enlargement is merely inflammatory and when it is due to some more serious lesion, particularly *tuberculosis* on the one hand and *lymphadenoma* or *lymphosarcoma* upon the other. The longer the glandular swellings persist, the less likely is it that they are purely inflammatory. The younger the patient, and the more unsterilized cow's milk he has been drinking, the more likely are they to be tuberculous. If they are present on both sides of the neck, tend to become adherent to one another and to the skin, and are tender notwithstanding their having been present for some time, they are probably tuberculous, and the diagnosis will be settled by surgical measures, the affected glands being excised and examined microscopically. Spontaneous breaking down of the glands, with a red indolent condition of the skin around a discharging fistula, and very slow healing, are developments to be forestalled whenever possible: but if they have occurred the condition is almost certainly tuberculous in cases in which there is no question of a late stage of malignant disease. There may be confirmatory evidence in the shape of tuberculous lesions elsewhere, especially in a joint, the spine, or the peritoneum. It is noteworthy that cases of tuberculosis of the glands are even less likely than other individuals to develop ordinary phthisis, so that the absence of lung signs is no indication that the

glands are not tuberculous. Lymphadenoma is sometimes so restricted in its earlier lesions as to effect the cervical lymphatic glands to a great extent, and long before any other groups are involved; in such cases, previous to operation and microscopical examination, the nature of the glandular enlargement may be open to great doubt; even after an operation there may be differences of opinion, though the large-celled hyperplasia in Hodgkin's-disease glands is distinguishable by experts from the giant-cell changes of tuberculosis. Clinically, the two are distinguished by the fact that tuberculous glands become matted together and adherent to the skin, while Hodgkin's-disease glands remain separate from one another and do not soften or break down even when they have become of such great size that, had they been tuberculous, they almost certainly would have done so; consequently, they do not become adherent to the skin, to one another, or to the deeper parts, and they do not cause a fistulous discharge. Enlargement of the spleen as well as of the lymphatic glands in the neck would indicate Hodgkin's disease rather than tubercle.

Secondary carcinoma of the glands in the neck is easy to diagnose when the past or present existence of a primary growth is known, generally a squamous-celled carcinoma (epithelioma) of the tongue, lip, gum, cheek, face, palate, pharynx, larynx, or œsophagus. Cases in which an œsophageal growth has not caused stenosis may give rise to doubt, for secondary deposits in the glands may be the first indication that anything is wrong. The patient's age will generally suffice to make tuberculosis unlikely, for tuberculous glands are far commoner in children than in adults, whilst carcinoma is a disease of the middle and later periods of life; the rapid enlargement of the glands, their extreme hardness, the way they become fixed to the deeper structures as well as to the skin, and their ultimate ulceration and fetid stench will leave no doubt as to their character.

Sarcomatous glands in the neck are much rarer; the chief variety is referred to above as acute lymphadenoma, between which and lymphosarcoma there is no distinctive difference.

Supraclavicular Glands. When the glands immediately above the clavicle, especially those on the left side in the region of the attachment of the sternomastoid muscle, are enlarged without affection of other lymphatic glands in the neck, they suggest a *primary new growth in the abdomen*, with secondary deposits ascending along the course of the thoracic duct to infect the glands close to where the thoracic duct enters the junction of the left jugular and left subclavian veins. There are, of course, many cases of abdominal malignant disease in which these glands do not become affected at all; but the value of the sign when it does occur is considerable (*Fig. 77*, p. 66). No one variety of intra-abdominal carcinoma is more liable than another to produce secondary deposits here; the primary seat may be the stomach, gall-bladder, pancreas, duodenum, colon, rectum, ovary, testicle, kidney, or suprarenal; excision and microscopical examination of the left supraclavicular gland may indicate the site of the primary growth. The right supraclavicular gland may be enlarged in a similar way, but less often—generally not as the result of intra-abdominal but of *intrathoracic new growth*, particularly squamous-celled carcinoma of the œsophagus. When the supraclavicular glands are affected at the same time as the axillary glands, in cases of cancer of the breast, the condition is important as indicating that the disease has extended beyond the limits within which operative cure is likely to be possible.

Axillary Glands. The three main causes for enlargement of the glands in one axilla without enlargement of the glands elsewhere are: *Septic absorption* from sore places upon the fingers, arm, breast, shoulder, or upper part of the back; *secondary deposits* of carcinoma from the breast; and *lymphadenoma*. *Tuberculous* axillary glands without obvious affection of those in the neck have been recorded, but they are uncommon. Sometimes the source of septic absorption is by no means obvious; it may be no more than inflammation around a rag nail. Inflammatory glands are generally painful, and they are associated with more or less pyrexia. Lymphatic leukaemia will be excluded by the absence of pathognomonic blood-changes; the breasts should be palpated carefully lest an unsuspected carcinoma be present, already infecting the axillary glands with secondary malignant disease; Hodgkin's disease will only suggest itself if inflammatory absorption, secondary growth, tubercle, and malignant disease can be excluded, but to clinch the diagnosis excision and histological examination of one of the glands may be required; if the case is one of Hodgkin's disease other lymphatic glands will presently become enlarged

also (see *Fig. 380*, p. 471); particularly those in the neck of the same or opposite side, and those in the other axilla; and the spleen will very likely enlarge too.

Epitrochlear Glands.—The only important cause of enlargement of the epitrochlear gland is *microbic absorption* from the fingers, hand, or forearm: the site of primary infection may be in the skin—a whitlow, for example, a post-mortem wound, or a dissecting-room sore; or it may be more deep-seated, as in cases of infective synovitis, arthritis, or peri-arthritis. It is important not to mistake for a simple whitlow such a lesion as a *digital chancre*, which may also cause enlargement of the epitrochlear gland before infection becomes general and the roseolar rash, sore throat, and other secondary symptoms indicate the nature of the case. Wassermann's serum reaction may not be positive at this stage, but the *Treponema pallidum* may be discovered in the sore bacteriologically. The relative chronicity of the apparent whitlow may be the chief thing causing one to recognize that it is a chancre.

Mediastinal and Bronchial Glands. These cannot be palpated: their enlargement is surmised when there are signs of something within the thorax obstructing one or other bronchus, or leading to laryngeal paralysis, or stenosis either of the innominate vein or of the superior or inferior vena cava. The diagnosis will be between *aortic aneurysm*, *chronic mediastinitis*, *syphilitic mediastinitis*, and *mediastinal new growth*. The X rays are almost essential in confirming the diagnosis, and in distinguishing enlarged malignant glands from aneurysm of the aorta (*Fig. 219*, p. 260). Inflammatory or caseous bronchial or mediastinal glands seldom if ever obstruct a bronchus in the way that malignant glands do, possibly because, before they have reached a sufficient size, they have softened and discharged their contents into the bronchial tube. When, as happens in rare cases, a caseous gland does obstruct a bronchus, it is noteworthy that it is less uncommon for a right bronchial gland to do this than a left.

Mesenteric Glands. It is seldom possible to palpate enlarged mesenteric glands, although the diagnosis that they are swollen may often be made upon circumstantial evidence. Any *inflammatory* condition of the bowel may lead to their being enlarged, particularly if there is any breach of the mucous membrane, as in cases of *ulcerative colitis*, *dysentery*, *tuberculosis of the bowel*, or *typhoid fever*. They are greatly involved in most cases of *tuberculous peritonitis*: the masses that are felt in the abdomen, however, are hardly ever the glands themselves, but rather extensive inflammatory and caseous matings of which glands may form the nucleus. *Malignant new growth*, such as primary carcinoma of the stomach or colon, ovary, uterus, or testis, may cause extensive secondary deposits in the mesenteric and retroperitoneal lymphatic glands, usually most marked in the immediate neighbourhood of the primary new growth, but extending thence in the direction of the liver until the portal glands are involved; but without opening the abdomen it is always difficult to determine whether the masses felt in cases of this kind are really enlarged lymphatic glands or are masses of new growth in the peritoneum or elsewhere than in the glands.

Iliac and Pelvic Glands.—What has been said in connection with mesenteric glands applies also: but it is more often possible to determine by palpation whether or not iliac lymphatic glands are affected. In cases of suspected *malignant disease*, characteristic nodules of secondary deposits in lymphatic glands may be felt sometimes on careful palpation of the iliac fossa or upon making a rectal examination.

Inguinal and Femoral Lymphatic Glands. The commonest cause by far of enlargement of the inguinal lymphatic glands and not of those elsewhere, is *septic absorption* from microbial foci in the regions whose lymphatic vessels drain into these glands: sore places should be looked for upon the toes, and between them, upon the feet, legs, thighs, buttocks, lower part of the back, scrotum, penis, perineal and vulval regions; and a urethral discharge, gonorrhoeal or otherwise, should also be sought for. Most of these cases will be associated with constitutional symptoms, especially pyrexia and loss of appetite, and with local pain and perhaps reddening of the skin over the inflamed glands. The latter may break down into abscesses—*huboes*.

Another, but far less common, cause for localized enlargement of the inguinal glands is *secondary carcinoma* secondary to squamous-celled carcinoma (epithelioma) of the scrotum, prepuce, penis, perineal region, anus, clitoris, labium majus, labium minus, vagina, leg, or foot. In such cases the diagnosis will become obvious when the primary

growth is found, and if doubt exists as to the nature of any such ulcerating sore the result of microscopical examination of a small portion excised should clinch the diagnosis.

Melanotic sarcoma is another rare but important cause of enlargement of the inguinal lymphatic glands: sometimes, when the primary growth is hardly larger than a pea, arising in connection with the skin of one of the toes, or perhaps a mole, the inguinal glands may be as big as pigeon's eggs, rapidly growing, and comparatively painless. The nature of this enlargement may be quite obscure unless the dark tinge of the growth can be seen through the skin, or there is melanuria (Fig. 181, p. 907), or a careful examination reveals a small primary but growth of the skin, or mole or surgical measures are adopted for their removal.

Popliteal Glands are situated just above the knee-joint, and are the largest of the lymphatic glands in the body. They are situated in the popliteal space, which is the space between the femur and the tibia, and are the largest of the lymphatic glands in the body. They are situated in the popliteal space, which is the space between the femur and the tibia, and are the largest of the lymphatic glands in the body.

Lymphatism or Status Lymphaticus.—Lymph glands are often enlarged in children, and young persons who have had the smallpox. Representing the status *lymphaticus* are other general anæsthetics, and of which neither children nor adults are exempt. The cause is inadequate operative measures, wounds, removal of tonsils, or removal of glands, of the internal lymphatic glands and the lymphatic ducts. The lymphatic glands are enlarged, the mesenteric glands, Peyer's patches, and the mesenteric follicles of the intestine are enlarged, and may be considerably larger than in health. The state of affairs here being described as the status lymphaticus, or lymphatism, and is regarded by some as being pathological. It is doubtful, however, whether this is not really the normal condition of the lymphatic tissues at this age, for very similar appearances are to be found in the bodies of children killed, not slowly by disease, but suddenly by accidents. In any case, it is almost impossible to diagnose the so-called status lymphaticus during life, for if it is an affection at all it is one of the internal lymphatic tissues and not of the palpable and easily palpable lymphatic glands. It is doubtful, however, if it is really a pathological state, though deaths produced by anæsthetics or minor operations are frequently attributed to it.

Herbert French.

MACROGLOSSIA. (See SWELLING OF THE TONGUE, p. 851.)

MACROSOMIA. (See GIANTISM, p. 323.)

MACULES are circumscribed discolorations or decolorizations of the skin without noticeable elevation or depression. They may be due : (1) To the passage of blood, or of the colouring matter of the blood, into limited areas of the skin, as in purpura : (2) To hyperæmia, either arterial or venous, as in erythema : (3) To dilatation of the vessels of the skin, or the formation of new vessels, as in capillary nevus and telangiectases : (4) To changes in the pigmentation of the skin, whether of the rete or of the corium—on the side of excess as in chloasma, or on that of deficiency as in leucoderma : and such changes may result from the administration of drugs such as arsenic and chloral, or may be an expression of trophoneurosis, as in glossy skin.

Macules of the second and third groups are effaced temporarily by pressure; those of the first and fourth remain unaltered.

Macules may be inflammatory as in the rose spots of enteric fever, or non-inflammatory as in purpura : congenital as in moles, or acquired as in the exanthemata : temporary as in drug rashes, or permanent as in leucoderma : scanty as sometimes in leucoderma, or abundant as in roseola. They may be attended by subjective symptoms (e.g., itching) as in drug rashes ; but generally there are no such accompanying symptoms. Usually round or roundish, they may be oval, or irregular : they also vary greatly in definition. In colour they may be red, brown, or yellow, in various shades. In size they vary from a mere speck to, say, the area of a man's hand : if very widely diffused, as in malaria, the pigmentation is usually styled a discoloration. Most frequently a primary lesion, as in lentigo, the macule may also be secondary to burns, blisters, excoriations, and eruptions of various kinds, erythematous, vesicular, bullous, papular, pustular and eczematous.

The brown spots which follow traumatic or purpuric ecchymoses, hæmorrhagic urticaria, varicose eczema, etc., form a special group of macules in which the pigment is hæmosiderin. If a macule takes on a slight degree of elevation it is sometimes styled a maculo-papule.

The differential diagnosis of the erythemas, of which the lesions are for the most part too diffuse to be regarded as macules, is set out in the articles on ERYTHEMA (p. 275) and NODULES (p. 500); that of the purpuras in the article on PURPURA (p. 675); that of leucodermia, sclerodermia, morphea, the various forms of chloasma, and the discolorations due to the use of drugs, in the article on PIGMENTATION OF THE SKIN (p. 642). Nor need the most familiar macule, that which occurs in lentigo (freckles), be described here, for the only affection with which it can be confused is xeroderma pigmentosum, the diagnosis from which is given under TUMOURS OF THE SKIN (p. 886), where also will be found the differential diagnosis of another macular affection, xanthoma in its various forms. Tinea

versicolor has been dealt with under FUNGUS AFFECTIONS OF THE SKIN (p. 313); pityriasis rosea under SCALY ERUPTIONS (p. 746); lichen planus and herpes, both of which may be followed by macular stains, respectively under PAPULES (p. 597) and VESICLES (p. 913). Of naevi and of telangiectases the identification is self-evident, and it only remains to speak of the macules of leprosy and syphilis.

In *leprosy*, following the prodromal symptoms and the period of invasion, erythematous spots appear on the face, limbs, or trunk, varying in colour according to the natural pigmentation of the skin, but usually in white races of a light red. The colour is brightest at the edge; the centre may become white and atrophic. In size the macules vary from a pin's head to the palm of the hand, or larger; they are smooth and shining, with a well-defined outline. Some infiltration is usually present. Fresh crops continue to come out at irregular intervals, and each outburst is accompanied by an exacerbation of the constitutional symptoms. After a time the macules and the neighbouring areas of apparently normal skin become more or less anæsthetic. The macular stage of leprosy may possibly be confused with *erythema simplex*, but the macular

Fig. 383. Macular syphilide.

areas are usually larger than in erythema, in which also there is little or no constitutional disturbance. As soon as anæsthesia arises the diagnosis is settled. This is indeed the crucial test in all cases of doubt as between leprosy and any other affection, for in leprosy it is almost invariably present, if not in the lesions themselves, then in some neighbouring area of the skin. Its commonest sites are towards the centre of the macule, in the pale patches left by macules that have disappeared, and in the hands and feet. Another distinctive feature of leprous spots is that they rarely perspire. In *syringomyelia* the sensory and trophic lesions may suggest leprosy, but the macules will be absent, nor is there enlargement of lymphatic glands or thickening of nerve-trunks. (For the diagnosis of nodular leprosy from lupus vulgaris, see under NODULES, p. 590.) Whenever doubt exists the lepra bacillus should be sought in the lesions or in the nasal discharge.

The *macular syphilide* is one of the most characteristic lesions of secondary syphilis.

The eruption (*Fig. 383*), erythematous in character and styled syphilitic roseola, begins as a macular mottling, resembling measles but rather more dusky, distributed over the chest and abdomen. It is often evanescent, disappearing in a few hours and coming out again as suddenly. The mucous membrane of the throat is the seat of a similar eruption, and superficial ulcers may form on the tonsils. Generally about a fortnight from its appearance the rash begins to fade, giving place to a papular or follicular eruption on trunk, limbs, face, and neck. Hyperæmia of the papillæ here and there gives rise on the chest and abdomen, and often on the flexor aspects of the limbs, to red patches which may persist for a longer or shorter time as isolated blotches, varying in colour from a delicate rose to a pale violet or dusky-bluish or even brownish-red. Scattered about among these macular syphilides may often be seen papules (maculo-papular syphilides), which leave stains of varying depth.

From the macular syphilide both *tinea versicolor* and *tinea circinata* may be distinguished by the detection microscopically of the fungous parasites present in the lesions of those affections, and, in the case of *tinea versicolor*, by the ease with which the scaly patches can be detached by the finger-nail: the erythematous *drug rashes*, such as those produced by *copaiba*, by their more vivid redness and the presence of itching and burning; *seborrhœa corporis* by its more limited distribution; *measles* by the crescentic character of the eruption, the coryza, cough, and the different distribution. A peculiarity of this syphilide, which should always be watched for in doubtful cases, is that it varies in colour with the temperature; a cool atmosphere will bring it out in vivid colours even when almost completely faded.

Ernest Dore.

MAIN-EN-GRIFFE. (See CLAW-HAND, p. 141.)

MALLET FINGER is a condition in which the terminal phalanx is maintained in a position of acute flexion, and it is generally diagnosable at sight: it is the cause that may be in doubt. It is usually the result of injury, but may ensue from inflammatory damage of infective rheumatoid type: in each case the deformity is due either to detachment of the insertion of the extensor aponeurosis into the base of the dorsal aspect of the terminal phalanx, or to stretching and attenuation of this aponeurosis, so that the flexor tendon attached anteriorly to the base of the terminal phalanx draws the latter into the position of acute flexion.

Herbert French.

MARASMUS literally means 'wasting', and therefore signifies much the same as loss of weight. By common consent, however, when speaking simply of marasmus one generally has in mind an infant or young child, so that lesions which cause loss of weight in tender years will be considered under the present heading, whilst wasting in older patients is discussed under the heading *Wasting*, Loss of, p. 932.

The bodies of infants and young children consist so largely of water that great variations may occur within a comparatively short time, particularly in association with a disease which causes loss of fluid. The most rapid loss of weight occurs as the result of *acute diarrhœa*, with or without vomiting: in the summer zymotic diarrhœa of infants the subcutaneous tissues may be seen to shrivel in twenty-four hours or less, the eyes become sunken, the fontanelle depressed, and the patient loses weight rapidly. There are probably various micro-organisms producing these acute symptoms, of which the best known are the *Bacillus enteritidis* of Gaertner and Morgan's bacillus I., but the exact bacteriological diagnosis of the symptoms can be arrived at only by investigation of the stools and perhaps of the patient's serum in special laboratories. Acute vomiting without diarrhœa generally causes loss of weight, but less markedly than does severe diarrhœa: it sometimes does so to a considerable extent, nevertheless, particularly in that periodic type of the malady known as *cyclical vomiting of infants*. Without apparent cause, a child of tender years who is subject to this complaint is seized, without any preceding irregularity in diet and apparently without anything definite to account for the mischief, with most severe and recurrent vomiting, lasting for twenty-four, thirty-six, or forty-eight hours, or even longer, nothing whatever being kept down, and the urine at the same time abounding as a rule with diacetic acid and acetone, indicating acidosis (page 3). Severe though the loss of weight may temporarily be, the symptoms generally subside as rapidly as they come on, and the patient remains in apparently normal health until the

next period of similar vomiting with acidosis comes on. After a few years the attacks recur at longer and longer intervals, finally ceasing altogether in the same kind of way that recurrences of Henoch's purpura do. The malady is thought to be due, not to microbial infection, but rather to some variety of anaphylactic phenomenon, the little patient being as yet unduly susceptible to the ordinary metabolic products of ordinary foods, just as some individuals have life-long hypersensitiveness to the products of particular foods, such as strawberries or crab. Cyclical-vomiting children are more often girls than boys, and they are found in well-to-do families where special care is taken with dietaries, rather than amongst the poor. Apart from cyclical vomiting, severe attacks of vomiting may be caused by errors of diet of various kinds, though it is remarkable how children escape the disorders of injudicious feeding if only virulent organisms are not administered in the food at the same time. *Congenital hypertrophic stenosis of the pylorus* is nowadays spoken of as though it were itself a disease; it is associated with persistent vomiting of all foodstuffs, the symptoms coming on either immediately after birth or within a few days or weeks, and in not a few instances resulting in death from sheer inanition. At post-mortem examination in such cases there is undoubtedly both more muscle than there should be in the pylorus, and undue tightness of its constriction, but it is doubtful whether this is really a condition of *congenital* malformation, and not the result of spasm of the pylorus produced by injudicious feeding, especially the giving of food before the mother has milk in her breasts, and therefore a postnatal development: like cyclical vomiting it is a malady of the children of the fairly well-to-do rather than of the poor.

Simple *starvation* owing to inability of the parents to provide food will naturally cause acute wasting, though the nature of the case may not be obvious to the doctor unless the conditions of home life are known.

Defective feeding is one of the commonest causes of lack of progress and of actual marasmus amongst the children of the lower classes. The amount of dirt that reaches the child's mouth from its own fingers, from its mother's breasts, and from the utensils in which the food is given, may suffice to upset the digestion even if the right food be given in proper amounts and at the right intervals: when, in addition to the dirt, the food-supply is of the wrong kind and the intervals are irregular, it is not at all surprising that the child may not thrive.

Rickets is not so much a cause of marasmus as a concomitant effect of the injudicious feeding: many rickety children being, indeed, unduly fat and heavy.

Congenital syphilis, on the other hand, is a very potent cause for marasmus. The diagnosis may sometimes be guessed at: it may sometimes be obvious from the snuffles, skin lesions, Parrot's nodes, condylomata: syphilis may be known of in the parents or detected by Wassermann's serum test. Many congenitally syphilitic children, without developing any of the better known evidences of syphilis, fail from simple inability to thrive, and, although born fine, healthy-looking infants, presently waste and pine, and may be said rather to cease to live than in the ordinary sense to die of a disease.

Tuberculosis is a very important and common cause for loss of weight in infants, though it is often very difficult to be certain that a tuberculous lesion is present. No obvious foci such as tuberculous glands in the neck, kyphosis from spinal caries, ascites, or abdominal lumps from tuberculous peritonitis or *tubercles mesentericae*, tuberculous joints such as the hip or knee, tuberculous dactylitis, and so forth, may be present, and yet there may be some deep-seated lesion, of which the commonest is caseation of the bronchial glands. Phthisis pulmonalis is almost unknown in infancy and childhood: in phthisical patients there is practically never caseation of the bronchial glands: in infants and young children caseous bronchial glands are very common, and they occur almost entirely in those who have drunk quantities of unboiled milk. The danger in such cases is that the bacilli will not remain localized to the bronchial glands: many a child is quite unsuspected of having such a lesion until some intercurrent malady such as measles causes the mischief to light up and become generalized in the form of general tuberculosis and meningitis, and at the post-mortem examination caseous bronchial glands, obviously of long standing, are found. Many marasmic children recover completely, and the nature of the case at the time when there were loss of weight and general ill health may never be determined. The child outgrows its delicacy. It is always possible, or even probable,

when obscure wasting occurs in a child who objectively presents no particular abnormality except ill health, that the lesion is tuberculous absorption from infected milk, with accumulation of the bacilli in the mesenteric and bronchial glands. If the hands are held on either side of the child's neck and gently moved up and down, little pea-like nodular glands can often be felt in the posterior triangle in these cases; though not pathognomonic of tuberculous infection, these pea-like knots in the cervical glands are always suggestive. The occurrence of irregular pyrexia of obscure origin may give a clue to the diagnosis of glandular tubercle. X-ray examination of the thorax in the left oblique position may show shadows of the enlarged glands projecting into the posterior mediastinum behind the upper part of the heart (*Fig. 384*), though absence of such shadows does not prove that no tuberculous glands are present. Von Pirquet's skin reaction might also be tried, though its results are by no means pathognomonic (p. 932), especially if the tuberculin used is not prepared exactly as it was in Von Pirquet's original method.

Fig. 384. Skiagram showing a mass of viscous tuberculous glands in the right side of the mediastinum. The patient was a boy of 15 who developed a spontaneous pleural effusion. The skiagram shows at the same time the flattening and raising of the right side of the diaphragm which resulted from the pleural thickening when the effusion had become cured.

Herbert French.

MELÆNA is the term applied to the black, often tarry, motions that result from abundant hæmorrhage from some place high up in the alimentary canal, generally a *gastric* or *duodenal ulcer*; or *cirrhosis of the liver*; or after the *swallowing of blood* derived from *HEMORRHOIDS* (p. 358) or *EPISTAXIS* (p. 273). True melæna due to altered blood may be simulated by one or two other conditions that render the stools dark or black, notably after the taking of *charcoal* by the mouth either as biscuits or as animal charcoal used sometimes for medicinal purposes; after the eating of *bilberries*; after taking *iron* in large quantities by the mouth, the iron being converted into the sulphide; or after bismuth in amounts such as those administered for X-ray examination of the alimentary canal, though the slaty colour of stools containing sulphide of bismuth is not nearly so dark as is that of true melæna. Where there is doubt, a little of the black stool may be smeared on a small piece of lint, a few drops of fresh tincture of guaiacum poured on to one side of the black smear, and some active ozonic ether poured gently over the whole; in the presence of blood a bright blue colour will become apparent in the lint adjacent to where the black motion and the tincture of guaiacum have mingled.

Lesions lower down the bowel than the duodenum give rise to red blood in the stools rather than melæna; but occasionally one sees melæna instead of red blood when there has been hæmorrhage in *typhoid fever* from an ulcerated Peyer's patch in the upper ileum or from an ulcer in the jejunum; it is also possible to get melæna from either of two rare vascular lesions in the abdomen, namely, *embolism of an upper branch of the superior mesenteric artery*, generally a complication of infective endocarditis, and *thrombosis of an upper branch of the mesenteric vein*, the result as a rule either of abdominal injury or of some infective intra-abdominal trouble which has produced phlebitis. Direct *injury* to the abdomen by a blow or a crush may also cause bleeding from contused bowel high up and consequently melæna; the history indicates the cause.

Quite young infants are sometimes seized with illness, at a few days old, associated with the passage of black tarry motions containing altered blood *melæna neonatorum*; and death is apt to occur in the course of a few days unless serum injections are given subcutaneously, preferably serum from the father's blood. The precise nature of *melæna neonatorum* is uncertain; it may sometimes have an infective basis, but from the way it may be cured by the use of parental serum it would seem to be the result, in certain cases at any rate, of some intrinsic abnormality in the infant's hæmatopoietic arrangements.

The diagnosis is easy, the condition is rare, but it is important from the point of view of the consternation it produces in the family and in the doctor.

In adults, by far the commonest causes of melæna are gastric ulcer, duodenal ulcer, and cirrhosis of the liver. Carcinoma of the stomach causes much less copious bleeding as a rule, and leads to occult blood in the stools rather than melæna, though it occasionally leads to the latter. With gastric ulcer and with cirrhosis of the liver there will generally have been HÆMATEMESIS (p. 336) before the melæna is apparent; with duodenal ulcer there may have been hæmatemesis also, but there may have been none. If a patient is seized with sudden faintness and giddiness, to such a degree perhaps that he falls down and has to be carried home, this faintness recurring perhaps during the day, and being associated by blanching which is not temporary only, but persists after he is comfortably in bed and says he is feeling himself again; and if the next motion but one—that is to say, the motion passed after the pre-existing colon contents have been evacuated—is black and tarry, giving the tincture of guaiacum and ozonic ether reaction for blood, there is hardly any other diagnosis likely than duodenal ulcer with acute internal bleeding from it. If no motion is passed spontaneously, the black contents of the bowel may be obvious on one's finger on making a rectal examination, and the diagnosis of the cause of the faintness and blanching may be made rapidly in this way. *Herbert French.*

MELANURIA. (See URINE, ABNORMAL COLORATION OF, p. 902.)

MEMORY, LOSS OF.—(See AMNESIA, p. 24.)

MENORRHAGIA.—By this symptom is meant an excessive amount of the menstrual flow, or an undue prolongation of the time during which it takes place. It is important to remember that in this condition the patient is free from bleeding during the intermenstrual periods, the term METRORRHAGIA (p. 486) being reserved for bleeding which occurs between the periods. The careful distinction between these symptoms often serves to distinguish very important conditions, and they should on no account be confounded with one another or considered as the same entity. Pure menorrhagia is an important symptom of many well-defined conditions which do not, as a rule, give rise to irregular bleeding. Both these terms must be limited carefully to patients who menstruate, and must not be used for bleeding after the menopause. The term METROSTAXIS (p. 488) is the best for bleeding occurring after menstrual life has passed.

CAUSES OF MENORRHAGIA.

1. GENERATIVE SYSTEM	2. CIRCULATORY SYSTEM	3. NERVOUS SYSTEM
Uterine congestion	Uncompensated valvular disease of the heart	Excessive coitus
Endometritis	Cirrhosis of the liver	Prevention of conception
Inversion and flexion	Emphysema of the lungs	<i>A Single Excessive Period</i>
Fibromyoma	Disturbance of internal secretions	Fright
Salpingo-oöphoritis	Hypert thyroidism	Violent emotion
Subinvolution		Sudden changes of temperature
Chronic metritis	<i>The Circulation</i>	Cold bath
Polypus	Passive hyperæmia from:	Dancing
<i>Acute Infectious Diseases</i>	Constipation	Hunting
Influenza	Tight-lacing	Gymnastics
Enteric	Sewing machine work	Bicycling, etc.
Cholera		
Scarlatina	<i>The Blood Itself</i>	
Variola	Deficient coagulability	
Rheumatism	Scurbutus	
Malaria	Purpura	
Diphtheria	Hæmophilia	
Measles	Lymphatic leukaemia	
	Splenomedullary leukaemia	
	<i>High Blood-pressure</i>	
	Arteriosclerosis	

Perusal of the above table will make it clear that the causes of pure menorrhagia can be grouped under the three headings of diseases of the generative organs, circulatory organs, and the nervous system. In attempting to differentiate these causes from one another, the first point to ascertain is whether there is any disease of the generative system, and failing this, to make such systematic examinations as will place the cause under one of the other two headings.

1. In considering the **Generative System**, it is clear that some diseases will be easy to discover, others will require some special method of examination.

For instance, of all the causes of pure menorrhagia, *fibromyoma* of the uterus stands out by itself as the only important growth associated with this symptom, and a simple bimanual examination, as a rule, suffices to show that such a tumour exists, the chief characteristics of a fibromyoma of the uterus being these: the uterus itself is enlarged, and in almost every instance the enlargement is asymmetrical, the typical shape of the organ being altered; as there may be more than one tumour in the uterus, its shape may be exceedingly irregular: the consistence of the tumour is hard and unyielding as a rule, but pathological changes in these tumours are common, some of them leading to softening, others to cystic changes which may give a fluid thrill. The tumour and cervix always move together if the organ can be moved at all. The only difficulty in diagnosis, as a rule, lies in distinguishing a fibromyoma of the uterus from an ovarian cyst, and sometimes this is exceedingly difficult, for it is not always possible to say that a given tumour is actually the enlarged uterus. It must be remembered, however, that the symptom which has led to this difficulty is menorrhagia, and ovarian tumours almost never give rise to it. Ovarian tumours usually cause no disturbance of menstruation at all, unless they are double and destroy both ovaries completely, in which case they cause amenorrhœa. If the tumour cannot be diagnosed by simple examination, there still remains examination by the uterine sound. If no possibility of pregnancy exists and with pure menorrhagia pregnancy is impossible the sound may be passed into the uterus with every precaution against sepsis. In all cases of fibromyoma, the sound passes beyond the normal $2\frac{1}{2}$ inches, and it may pass as much as 6 inches, or even more. In cases of subperitoneal fibroids, the uterus may not be much enlarged, but in such cases menorrhagia is not usually present. In ovarian tumours the length of the uterine cavity is not increased unless a condition of endometritis co-exists, which is very uncommon; and if it did not exist, the amount of elongation of the uterine cavity would be small. In general, however, it is quite unnecessary to use the sound for the diagnosis of a fibromyoma.

Uterine Congestion and Endometritis. These lesions can only be inferred in cases of pure menorrhagia when the uterus is not enlarged to any appreciable extent, and when, in addition, there are leucorrhœa and backache. These three cardinal symptoms, Pozzi's syndrome, point always to endometritis, whatever other lesion of the generative system may be present. As a rule the subjects of these are married and have had pregnancies or abortions, but endometritis may occur in a virgin, the result of infection, without any pregnancy having taken place. The presence of endometritis cannot be proved without the removal of the endometrium and microscopical examination of sections of the material removed by curettage.

Retroversion and flexion of the uterus and salpingo-oöphoritis are very definite and obvious lesions which are associated with menorrhagia, but the actual prime cause is again endometritis and uterine congestion.

So also with *subinvolution*, which necessarily can only follow labour or abortion: though a relaxed uterine muscle and a dilated uterine cavity are present, endometritis and congestion are present, too, and are the real causes of menorrhagia. Chronic metritis is the name given to that condition of symmetrical enlargement of the uterus which in 95 per cent of the cases is due to chronic subinvolution.

Exanthemata. The various exanthems are liable to cause menorrhagia except in those instances where they give rise to anæmia. It has been shown bacteriologically that an acute endometritis may be set up by various zymotic diseases, and therefore it is not surprising that in some instances this condition becomes chronic and causes a lasting menorrhagia.

2. Circulatory System. Under this heading there can be no doubt that definite causes of menorrhagia exist, but in the absence of well-defined lesions of heart, liver, or lungs it

may be a matter of considerable difficulty to make a differential diagnosis. Any lesion of the heart, liver, or lungs which leads to back-pressure in the venous system may cause hyperamia of the pelvic organs and consequent excessive menstrual losses. It does not follow, however, that this will be the case, because the sufferers from these diseases are sometimes anæmic as far as the *quality* of the blood goes, and consequently may lack the stimulus to menstruate at all. However, it happens not uncommonly that menorrhagia is caused by uncompensated valvular lesions of the heart, cirrhosis of the liver, or emphysema of the lungs. *Passive hyperamia* of the pelvic organs may result from constipation, tight-lacing, or certain occupations such as the working of a treadle sewing-machine; but endometritis may also be present and be the real underlying cause of excessive flow.

Anæmia.—That the quality of the blood itself may be a cause of menorrhagia is undoubted, and particularly if it be deficient in calcium salts, leading to retardation of the coagulation-time. Modern methods of estimating coagulation-time enable us to distinguish these cases with some certainty, and thus point out a line of treatment. Unfortunately there is no simple clinical method. Doubt also has recently been thrown on the view that the calcium salts have any effect on coagulation-time. The well-known signs of *scorbutus* in its minor degrees, *purpura*, and *hæmophilia* may draw attention to cases of this class.

Menorrhagia in young girls at the time of puberty and commencement of menstruation depends upon *excessive ovarian activity*, and we must conclude, therefore, a disturbance of the balance between the internal secretions. It is often associated, too, with retardation of the coagulation-time of the blood, especially in the subjects of chilblains, cold hands and feet, 'dead fingers', etc. It must not be forgotten that young girls may have a malignant growth of the uterus, such as sarcoma, but this is more likely to cause irregular bleeding as well as menorrhagia.

Finally, *high blood-pressure* must be reckoned with as a cause of menorrhagia at any period of life, but particularly when nearing the onset of the menopause. Menopause menorrhagia much more often depends upon one of the well-defined lesions of the uterus described above than on high blood-pressure, but cases occur in which the blood-pressure is alone responsible. The arteriosclerosis which is likely to affect the uterine vessels about this period of life may contribute to the causation of menorrhagia. The high blood-pressure, and possibly the arteriosclerosis also, may eventually prove to be connected with the internal secretions of the ductless glands. Though still mainly a matter of theory, normal menstruation depends in part at least on the normal balance being preserved between the various internal secretions, the ovarian and thyroid on the one hand being balanced by the suprarenal and pituitary on the other, and any disturbance of this balance may result in amenorrhœa, as in myxœdema, or in menorrhagia, as sometimes occurs in *exophthalmic goitre* and at the menopause. Menorrhagia is not infrequently the result of hyperthyroidism, without any sign of exophthalmic goitre. This condition may occur in young people as well as middle-aged; it can only be recognized by carrying out a test to determine the basal metabolic rate. It is very fascinating to believe that high blood-pressure may be due to the unbalanced action of the suprarenal and pituitary glands, and to suggest a remedy in consequence. In the absence, however, of collateral signs of definite lesions of ductless glands, we have at present no ready means of telling which gland is at fault.

3. **The Nervous System** alone is never likely to be a cause of lasting menorrhagia, but that a single profuse period may result from such disturbance of the nerve mechanism of menstruation has long been believed. There certainly are cases in which no other causation can be recognized, and in which the excessive flow is not repeated. The effect of sexual intercourse upon the menstrual flow is difficult to determine, but cases do occur in which excessive menstruation has been cured by abstinence, and we cannot but believe that excesses in this direction must therefore have been the cause. Such cases occur chiefly in the newly married. The part played by incomplete coitus, coitus interruptus, or prevention of conception by other means, is still difficult to determine, but we have no *real* evidence to hand which proves that any menstrual disturbances arise on these accounts. In any case, however, we are not justified in assuming that the nervous system is to blame for a menorrhagia until, by careful examination, we have eliminated the other more important causes.

T. G. Stevens.

MENSTRUATION, ABNORMALITIES OF. (See AMENORRHOEA, p. 22; DYS-MENORRHOEA, p. 237; MENORRHOAGIA, p. 482; and METRORRHOAGIA, p. 486.)

MERYCISM means cud-chewing or rumination, a symptom that is rare in man; even when it does occur it is no evidence of disease. It has to be distinguished from pyrosis and from flatulence; in typical cases there is no difficulty, for with merycism the act may be voluntary to some extent, actual food returns to the mouth instead of merely acrid fluid as in pyrosis, and there is none of the belching of flatulence. It sometimes develops in several members of the same family, either as a congenital peculiarity, or as the result of imitation. The diagnosis depends mainly upon the patient's own account of what he feels taking place inside him, upon the history of a similar condition affecting other members of the family, and upon the absence of objective evidence of gastric, intestinal, intracranial, or renal disease.

Herbert French.

METEORISM, or tympanites, is the term used to denote enormous distention of the abdomen with gas, the latter generally being within the alimentary canal, though it may be free in the peritoneal cavity. It is seldom itself of diagnostic importance, the nature of the case being determined usually on other grounds; but it may be very distressing to the patient, and it is often of grave omen. It is apt to be very troublesome in cases of *general peritonitis*; the diagnosis will depend upon the history, which will probably suggest a cause for peritonitis, such as gastric or duodenal ulcer, appendicitis, or typhoid fever; and upon the persistent vomiting, the dry furred tongue, the motionless rigid abdomen, the rising rapidity of the pulse, the facies Hippocratica, the impairment of note in the flanks, the rub over the liver or spleen, and the absence of borborygmi.

Intestinal obstruction, whether acute, subacute, or chronic, and whether due to strangulated hernia, peritoneal band, volvulus, new growth, intussusception, or other cause, often leads to extreme meteorism, with visible peristalsis, the passage of neither faeces nor flatus, and persistent vomiting which will become feculent if the case is not operated upon. Peritonitis ultimately supervenes; but previous to this intestinal obstruction is differentiated from general peritonitis by the absence of rigidity of the abdominal wall, by the presence of borborygmi and visible peristalsis, the absolute constipation in spite of enemata, the slower pulse, and the relatively better condition of the patient.

Acute pancreatitis, whether hemorrhagic or not, may cause acute meteorism. The symptoms are variable, but they nearly always suggest an acute abdominal condition requiring immediate laparotomy, the diagnosis being then suggested directly the areas of fat necrosis are seen in the omental fat. Previous to laparotomy the symptoms are rather those of acute intestinal obstruction than of general peritonitis; the usual history of acute pain in the epigastrium may at first suggest perforated gastric ulcer, but the abdomen remains supple as in obstruction more often than it becomes rigid as in peritonitis.

Meteorism in cases of *typhoid fever*, *dysentery*, *dengue*, and other severe illnesses in which the bowel is affected is chiefly of importance in that it may lead to an erroneous suspicion of perforation and general peritonitis. The diagnosis is often very difficult, and there may be grave anxiety and doubt as to whether the abdomen should be opened or not. One important point in typhoid fever is that perforation is generally accompanied by a sudden drop in the temperature and an equally sudden rise in the pulse-rate, whereas meteorism by itself would not cause this.

When the vessels in the mesentery are affected by *thrombosis* or *embolism*, acute meteorism results, with all the signs of intestinal obstruction; in milder cases recovery may ensue spontaneously after days of anxious watching; in severer cases peritonitis develops and the nature of the case may be quite obscure until laparotomy is performed, unless the existence of a cause is known, such as fungating endocarditis. *Atheroma* of the abdominal aorta or its main branches, in elderly people, sometimes leads to bouts of subacute or even quite acute abdominal symptoms known as *angina abdominalis*, during which meteorism, vomiting, and severe and recurrent colic-like pains all over the abdomen or localized now here now there at different times, may produce a

clinical picture so like either acute obstruction or acute peritonitis that laparotomy is very apt to be performed. The diagnosis can seldom be made in a first attack, but when similar bouts recur and yet subside without catastrophe the nature of the case may sometimes be guessed at: though the guessing may still leave doubt as to the possible presence of other causes such as gall-stones, appendicular colic, partial obstruction, or the like.

Interference with the *solar* and *mesenteric plexuses of nerves* has sometimes led to severe meteorism in cases of *tuberculosis mesenterica*, or infiltrating intra-abdominal new growth. The symptom occurs late, and the diagnosis will generally have been made on other grounds.

Affections of the *spinal cord* may lead to paralysis of the bowel and tympanites. This may result from transverse 'myelitis', whether due to primary softening of the cord from syphilitic or other spinal arterial thrombosis, from compression by spinal caries, new growth, or aneurysm, or from destruction of the dorsal region of the cord by a stab, a crushing, or a bullet wound. There will generally be PARAPLEGIA (p. 621) to indicate the nature of the case.

Diabetes mellitus often indicates its impending termination in coma by the onset of abdominal pains, with more or less meteorism. The diagnosis will be known already on account of the glycosuria. Meteorism is also common in the late stages of *cirrhosis of the liver*.

Particular mention may be made of *Hirschsprung's disease*—idiopathic enormous

Fig. 385. Hirschsprung's disease, or idiopathic dilatation of the colon. Note the distended coils of large intestine. (From Professor Rutherford Morrison's 'Introduction to Surgery'.)

distention of the sigmoid colon in children and young people (Fig. 385). Careful examination indicates that the enormous gaseous distention of the abdomen is not due to general tympanites, but to ballooning of what may seem at first to be stomach, but which is proved not to be this by the absence of immediate effect on the gas-containing cavity when fluid or gas is given by the mouth, by the swelling appearing to arise from the left iliac fossa, and if need be by the X-ray shadows after a bismuth meal. Obstinate constipation, or symptoms of recurrent intestinal obstruction, are

usual in these cases, and the diagnosis is confirmed by the laparotomy that is generally required, in the end, to relieve the patient.

Neurosis, or rather functional derangement of the nervous system, can lead to almost any symptom, including meteorism. Two difficulties arise in the diagnosis—namely, to be sure: (1) That the condition is meteorism at all, and not pregnancy, ascites, ovarian cyst or other tumour—phantom tumours are difficult to diagnose without examination under an anæsthetic, and even laparotomy may be undertaken before the absence of a tumour is established certainly; and (2) That the meteorism has no organic basis—the circumstances may sometimes suggest this at once, but in some cases the exclusion of an organic cause for the tympanites may take much time, careful inquiry into symptoms and physical signs, and considerable anxiety meanwhile.

Herbert French.

METHÆMOGLOBINURIA. (See HÆMOGLOBINURIA, p. 357.)

METRRORRHAGIA means loss of blood from the uterus in the intermenstrual periods, and the term should be applied only to irregular hæmorrhages during menstrual life. It is not correct to apply it to hæmorrhages connected with pregnancy, for menstruation is then in abeyance. It may, however, be used with propriety in those cases remotely connected with pregnancy in which menstruation has been re-established. The term may be used for losses of actual blood, or for blood-stained discharges in which mucus is mixed with the blood.

CAUSES OF METRORRHAGIA.

1. GENERATIVE SYSTEM

2. CIRCULATORY SYSTEM

3. NERVOUS SYSTEM

Malignant Growths :

Carcinoma
Squamous epithelioma
Sarcoma
Chorion-epithelioma

High blood-pressure due to :

Internal secretions
Arteriosclerosis

Sexual excess

Benign Growths :

Submucous fibroid
Fibroid polypus
Mucous polypus

At the menopause :

Undue congestion due to :
Internal secretions
Deficiency of calcium at
the onset

Inflammatory Lesions :

Erosion of cervix
Endometritis
Tuberculosis of the uterus

Blood Changes :

Purpura
Scurbutus
Hæmophilia
Leukæmia

1. **The Lesions of the Generative Organs** which give rise to metrorrhagia are well defined as a rule, and in the case of growths of the cervix uteri are often self-evident. Where growths of the body of the uterus are present, differential diagnosis is often a matter of great difficulty, and in many instances cannot be made without a preliminary curettage and microscopical examination of the material removed. In fact, with the exception of obvious mucous polypi, fibroid polypi, and advanced growths of the cervix, all the growths of the uterus require a preliminary histological examination for their exact diagnosis unless the symptoms demand a radical operation. In such cases it is sufficient to diagnose the actual nature of the growth after removal. It is not out of place here to suggest the best way to make histological preparations from curetted material, a matter of great importance to the patient, because it is often difficult to distinguish between cancer and endometritis unless the very best microscope sections can be secured. The curetted material must be obtained after dilatation, with a sharp curette, and the larger the fragments removed the more easy will the histologist's work be. Anæsthesia is always essential except in the case of cervical growths. In doubtful cervical growths a wedge should be cut out, including some normal tissue if possible. Curetted fragments should be washed free from blood for a minute or two, but should not be left to soak in water. They should then be placed immediately in an efficient fixing fluid, and the best all-round fluid for this purpose is formalin 10 c.c., 0.75 per cent salt solution 90 c.c. Twenty-four hours in this fluid gives good fixation, after which the tissues can be dehydrated in successive strengths of alcohol, cleared in xylol, and finally embedded and infiltrated with paraffin wax. Sections cut from these paraffin blocks are the best obtainable, far superior to any freezing method or celloidin infiltration. If the stained sections are submitted to a histologist who has experience of uterine growths, there should not be 2 per cent of doubtful specimens. If, however, the tissues are fixed improperly, thick sections are cut, and stained badly, then the most skilled histologist will be unable to give a definite and reliable diagnosis.

Cancer of the body of the uterus, cancer of the cervical canal, early cancer of the cervix, sarcoma of the uterus, chorion-epithelioma, some sloughing fibroids, tubercle, and endometritis can be distinguished from one another only by investigations carried out on these lines. The fact that all these lesions produce metrorrhagia, and may give rise to hæmorrhage on coitus, walking, straining at stool, and bimanual manipulation of the uterus, makes it imperative that we should have histological confirmation of the nature of the lesion before making an exact diagnosis.

The relation of *fibromyoma* to metrorrhagia as opposed to pure menorrhagia, which is the rule with these tumours, is interesting. Fibroids only produce irregular bleeding when they are submucous and in process of extrusion, when they are infected and sloughing, or when they are actually polypoid. The reason for this is that in these conditions the tumours are always partly strangulated by uterine contractions, and therefore in a state of gross venous congestion; hence they bleed more or less constantly, without

provocation. The occurrence of irregular bleeding in a person who is known to have fibroids almost always means one of these conditions, and, commonly, extrusion of the tumour from the uterus. On the other hand, it must not be overlooked that carcinoma may develop in the endometrium with a fibroid also present, or that a fibroid may become sarcomatous, or that a sarcoma may arise *de novo* in the uterus and attack a pre-existing fibroid. Rapid enlargement of a uterus, with irregular hæmorrhage, is very suspicious of a *sarcoma*, but as it is not uncommon for several fibroids to be present in the same uterus, it is also common for rapid enlargement to occur as a result of cystic changes in one of them, whilst hæmorrhage may take place due to extrusion of another.

Pure *carcinoma of the body of the uterus* rarely produces much enlargement of the organ, and any increase in size is not very rapid.

Chorion-epithelioma follows hydatidiform mole in about 50 per cent of the recorded cases, and it always follows pregnancy, never having been seen in the uterus in a case where pregnancy could be excluded. It is associated especially with profuse bleeding and the rapid development of a fetid discharge due to decomposition of blood and necrosing tissues in utero. Carcinoma of the body of the uterus rarely produces foul discharges until the condition is very advanced and has become exposed to the air.

The differential diagnosis of bleeding due to *cancer*, *erosion*, and *tubercle of the cervix* is often difficult in the early stages. In advanced cancer the friable hardness of the growth distinguishes it at once from the tough leathery hardness present in erosions. In the former, the growth can be broken down with the finger; in the latter, the soft velvety erosion can be scraped off the tough leathery and fibrous cervix beneath. Nothing, however, but sections made from wedges removed from the cervix enables us to distinguish cancer or erosion from tubercle in the early stages. Tubercle of the cervix is usually mistaken for cancer, but the difference is clear enough in microscope sections.

Mucous polyp and *fibroid polyp* are common causes of intermenstrual bleeding, and are usually quite definite growths. The mucous polypus is soft, strawberry-red in colour, often pedunculated, and contains cystic spaces filled with glairy mucus. It never gives rise to a malignant growth. The fibroid polypus is hard, and shows the glistening, whorled appearance so well known in fibromyomata on section. These growths are liable to infection and sloughing, and are then apt to be mistaken for cancer or sarcoma. The microscope alone will enable the difference to be made out.

Endometritis rarely causes severe metrorrhagia, but is often associated with a blood-stained watery discharge. In a doubtful case there is absolutely no way of distinguishing it except with the microscope.

2. The Circulatory System is sometimes responsible for metrorrhagia, just as it is for MENORRHAGIA (p. 482), and the actual causes are much the same. It is, however, especially at the onset and the decline of menstruation that irregular bleeding is likely to occur from this cause. The same disturbance of the internal secretions which may cause menorrhagia at these periods sometimes acts similarly in causing irregular bleeding. It is fairly common to find young girls at the onset of menstruation having menorrhagia and metrorrhagia, and it is often very difficult to be certain of a cause. It depends, however, very largely on two definite factors, namely: (1) Unusual uterine congestion, the result of an excess of the biochemical stimulus (internal secretions) of menstruation; and (2) Deficient coagulation power, possibly due to a want of calcium in the blood. The former cannot be diagnosed by any defined investigation, but the latter is determined by estimating the coagulation-time. Purpura, scorbutus, and hæmophilia are diagnosed readily when they act as causal agents. Leukæmia is sometimes responsible for irregular uterine bleeding, and is diagnosed readily by making a total and differential leucocyte count (pp. 32, 33).

3. Lesions of the Nervous System seldom cause metrorrhagia, but there is no doubt that sexual excess, often seen in the first months of married life, is a reflex cause of uterine congestion, and may cause metrorrhagia as well as menorrhagia.

T. G. Stevens.

METROSTAXIS is the term applied to uterine hæmorrhage at any period of life unconnected with menstruation, or at times when menstruation is in abeyance. It is convenient to keep this form of hæmorrhage separate from the other varieties, because in this way all the pregnancy hæmorrhages can be differentiated. Its cause may be classified according to whether the uterus is pregnant or not. The bleeding which occurs

from the vagina occasionally in new-born infants is usually thought to depend upon uterine congestion subsequent to the cessation of the placental circulation. It is usually trivial, but a fatal case has been reported.

CAUSES OF METROSTAXIS.

UTERUS NON-PREGNANT

Uterine bleeding in the new-born
Malignant growths
Polypi
Senile endometritis
Senile granular vaginitis
Pyometra
Secondary post-partum hemorrhage
Subinvolution
Chorion-epithelioma

UTERUS PREGNANT

Threatened abortion
Inevitable abortion
Incomplete abortion
Carneous mole
Hydatidiform mole
Ante-partum hemorrhage
Extra-uterine gestation
Malignant growths of cervix or vagina
Erosions
Polypi.

The differentiation of *malignant growths*, *polypi*, and *senile endometritis* can only be established in the same way as in cases occurring during menstrual life (pp. 487-8). *Senile adhesive vaginitis* must not be overlooked as a possible cause: the vaginal walls at the fornices become inflamed and form granulation tissue which may bleed if the surfaces rub together. On examining such cases the surfaces may be partly adherent, and the separation brought about by the finger may cause bleeding. In any doubtful case, the routine dilatation and curettage of the uterus must never be omitted. An unsuspected *pyometra*, or distention of the uterus with pus, may cause hemorrhage, along with a foul discharge, and although it is almost always accompanied by a malignant growth, may be only the result of infection and granulation-tissue formation.

In relation to a recent pregnancy, hemorrhage may result from simple subinvolution, from retained products of conception, and from chorion-epithelioma. The differentiation of these conditions can be established only by exploration of the uterine cavity, with, if necessary, the assistance of the microscope. Such conditions may be termed secondary post-partum hemorrhage in cases occurring within a few days of delivery.

Hemorrhage from the pregnant uterus almost always means separation of the placenta or of the embryo from its attachments, but malignant growths of the cervix, erosions, and polypi may have to be considered. Hemorrhage from a pregnant uterus is never due to malignant growths of the body of the organ, because pregnancy is practically impossible with such lesions. There are, however, two great difficulties in connection with pregnancy hemorrhages: these are to differentiate: (1) The uterine hemorrhage which occurs along with *extra-uterine gestation* from that due to *threatened abortion*: and (2) The bleeding of *placenta previa* from that due to the *separation of a normally situated placenta*.
